8. CONFLICT OF INTEREST

All members of the EAU Non-neurogenic Male LUTS Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website: <u>http://www.uroweb.org/guidelines/</u>. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

6.	CONFLICT OF INTEREST		91

1. INTRODUCTION

Urinary incontinence (UI) is an extremely common complaint in every part of the world. It causes a great deal of distress and embarrassment, as well as significant costs, to both individuals and societies. Estimates of prevalence vary according to the definition of incontinence and the population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost.

1.1 Aim and objectives

These Guidelines from the European Association of Urology (EAU) Working Panel on Urinary Incontinence are written by a multidisciplinary group, primarily for urologists, and are likely to be referred to by other professional groups. They aim to provide sensible and practical evidence-based guidance on the clinical problem of UI rather than an exhaustive narrative review. Such a review is already available from the International Consultation on Incontinence [1], and so the EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of UI. The focus of these Guidelines is entirely on assessment and treatment reflecting clinical practice. The Guidelines also do not consider patients with UI caused by neurological disease, or in children, as this is covered by complementary EAU Guidelines [2, 3].

The elderly

The Panel decided to include a separate but complimentary set of recommendations referring to the elderly population within each section. Older people with UI deserve special consideration for a number of reasons. Physiological changes with natural ageing mean that all types of UI become more common with increasing age. Urinary incontinence commonly co-exists with other comorbid conditions, reduced mobility, and impaired cognition and may require specific interventions, such as assisted toileting.

For the elderly person expectations of assessment and treatment may need to be modified to fit in with specific circumstances, needs, and preferences, while also taking into account any loss of capacity for consent. When the urologist is dealing with a frail elderly patient with urinary incontinence, collaboration with other healthcare professionals such as elderly care physicians is recommended.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urinary Incontinence Panel consists of a multidisciplinary group of experts, including urologists, a gynaecologist and a physiotherapist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: <u>http://www.uroweb.org/guideline/urinary-incontinence</u>.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Two scientific publications in the journal European Urology are also available [4, 5]. All documents are accessible through the EAU website: <u>http://www.uroweb.org/guideline/urinary-incontinence</u>.

1.4 Publication history

The EAU published the first Urinary Incontinence Guidelines in 2001. This 2017 publication presents a limited update of the 2016 Urinary Incontinence Guidelines.

1.4.1 Summary of changes.

Section 4.2 Pharmacological management has been revised for this 2017 print, including the addition of a new section 4.3.5.1 on Drug therapy.

Changed evidence summaries and recommendations can be found in sections:

4.2.1 Antimuscarinic drugs

Summary of evidence	LE
There is limited evidence that one antimuscarinic drug is superior to an alternative antimuscarinic drug for	1b
cure or improvement of urgency urinary incontinence.	
Higher doses of antimuscarinic drugs are more effective to cure or improve urgency urinary incontinence,	1b
but with a higher risk of side effects.	
Once daily (extended release) formulations are associated with lower rates of adverse events compared to	1b
immediate release ones, although similar discontinuation rates are reported in clinical trials.	
Dose escalation of antimuscarinic drugs may be appropriate in selected patients to improve treatment	1b
effect although higher rates of adverse events can be expected.	
Transdermal oxybutynin (patch) is associated with lower rates of dry mouth than oral antimuscarinic drugs,	1b
but has a high rate of withdrawal due to skin reaction.	

4.2.3.3 Recommendations for antimuscarinic drugs

Recommendations	GR
Offer antimuscarinic drugs for adults with urgency urinary incontinence who failed conservative treatment.	А
Consider extended release formulations in patients who do not tolerate immediate release antimuscarinics.	А
If antimuscarinic treatment proves ineffective, consider dose escalation or offering an alternative treatment.	В
Consider using transdermal oxybutynin if oral antimuscarinic agents cannot be tolerated due to dry mouth.	В
Offer and encourage early review (of efficacy and side effects) of patients on antimuscarinic medication for	С
urgency urinary incontinence.	

4.2.4 Antimuscarinic agents: adherence and persistence

Summary of evidence	LE
Adherence to antimuscarinic treatment is low and decreases over time because of lack of efficacy, adverse	2
events and/or cost.	
Most patients will stop antimuscarinic agents within the first three months.	

4.2.5 Antimuscarinic and beta3 agonist agents, the elderly and cognition

Summary of evidence	LE	
Antimuscarinic drugs are effective in elderly patients.		
Mirabegron has been shown to efficacious and safe in elderly patients.		
In older people, the cognitive impact of drugs which have anticholinergic effects is cumulative and		
increases with length of exposure.		
Oxybutynin may worsen cognitive function in elderly patients.		
Solifenacin, darifenacin, fesoterodine and trospium have been shown not to cause cognitive dysfunction in		
elderly people in short-term studies.		

4.2.5.2.13 Additional recommendations for antimuscarinic drugs in the elderly

Recommendations	GR
In older people being treated for urinary incontinence, every effort should be made to employ	С
nonpharmacological treatments first.	
Long-term antimuscarinic treatment should be used with caution in elderly patients especially those who	B*
are at risk of, or have, cognitive dysfunction.	
When prescribing antimuscarinic for urgency urinary incontinence, consider the total antimuscarinic load in	С
older people on multiple drugs.	
Consider the use of Mirabegron in elderly patients if additional antimuscarinic load is to be avoided.	С

*Recommendation based on expert opinion.

4.2.6 Mirabegron

Summary of evidence	LE
Mirabegron is better than placebo and as efficacious as antimuscarinics for improvement of urgency	
urinary incontinence symptoms.	
Adverse event rates with mirabegron are similar to placebo.	1a
Patients inadequately treated with solifenacin 5 mg may benefit more from the addition of mirabegron than	
dose escalation of solifenacin.	

Recommendation	GR
In patients with urgency urinary incontinence and an inadequate response to conservative treatments, offer	А
mirabegron unless they have uncontrolled hypertension.	

4.2.7 Drugs for stress urinary incontinence

Summary of evidence	LE
Duloxetine, 40 mg twice daily improves stress urinary incontinence in women.	1a
Duloxetine causes significant gastrointestinal and central nervous system (CNS) side effects leading to a	1a
high rate of treatment discontinuation, although these symptoms are limited to the first weeks of treatment.	

Recommendations	GR
Duloxetine can be used with caution to treat women with symptoms of stress urinary incontinence.	A
Duloxetine should be initiated using dose titration because of high adverse event rates.	А

4.2.8 Oestrogen

Recommendation	GR
Vaginal oestrogen therapy for vulvovaginal atrophy should be prescribed long-term. In women with a	С
history of breast cancer, the treating oncologist needs to be consulted.	

4.2.9.2.2 Monitoring for hyponatraemia

Recommendations	GR
Consider offering desmopressin to patients requiring occasional short-term relief from daytime urinary	A
incontinence and inform them that this drug is not licensed for this indication.	
Monitor plasma sodium levels in patients on desmopressin.	A*

*Recommendation based on expert opinion.

4.2.10 Drug treatment in mixed urinary incontinence

Recommendation	GR
Offer antimuscarinic drugs or beta3 agonists to patients with urgency-predominant mixed urinary	A*
incontinence.	
* Possemmendation based on everyt entrien	

*Recommendation based on expert opinion.

4.3.5.1 Drug therapy

Summary of evidence	LE
Duloxetine, either alone or combined with conservative treatment, can hasten recovery of continence but	1b
does not improve continence rate following prostate surgery.	

Recommendation	GR
Consider offering duloxetine to hasten recovery of continence after prostate surgery but inform the patient	В
about the possible adverse events.	

2. METHODS

2.1 Introduction

For the 2017 Urinary Incontinence Guidelines, the literature has been assessed for Section 4.2 – Pharmacological management. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between January 2012 and April 20th, 2016. A total of 1164 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <u>https://uroweb.org/guideline/urinary-incontinence/?type=appendices-publications</u>.

A systematic review was performed assessing nocturia and nocturnal incontinence in both men and women, in collaboration with the EAU Non-Neurogenic Male LUTS Guidelines Panel [6].

Due to the paucity of literature addressing nocturnal incontinence, the Panel did not include new information on this topic. The findings relating to nocturia in males are presented in the Non-Neurogenic Male LUTS Guidelines.

References used in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://www.uroweb.org/guideline/</u>. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

The current Guidelines provide:

- A clear pathway (algorithm) for common clinical problems. This can provide the basis for thinking through a patient's management and also for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance on what to do or not to do, in most clinical circumstances. This should be particularly helpful in those areas of practice for which there is little or no high-quality evidence.

In this edition the Panel has continued to focus, largely, on the management of a 'standard' patient. The Panel has referred in places to patients with 'complicated incontinence', by which we mean patients with associated morbidity, a history of previous pelvic surgery, surgery for UI, radiotherapy and women with associated genitourinary prolapse. An appendix is included on non-obstetric genitourinary fistulae. The subject of prevention of urinary incontinence has not been addressed. A systematic review on nocturnal incontinence found no studies on the topic. The Panel are of the opinion that nocturnal incontinence should be considered in future research studies.

2.2 Review

This document was subjected to peer review prior to publication in 2015. The decision for re-review is made based on the extent of the revision. A major revision resulting in significant changes to the clinical recommendations presented in the text will warrant re-review.

2.3 Terminology

Evidence summaries provide a succinct summary of what the currently available evidence tells us about an individual clinical question. They are presented according to the levels of evidence used by the EAU. Recommendations have been deliberately written as 'action-based' sentences. The following words or phrases are used consistently throughout the Guidelines;

• **Consider** an action. This word is used when there is not enough evidence to say whether the action causes benefit or risk to the patient. However, in the opinion of the Panel, the action may be justified in some circumstances. Action is optional.

- **Offer** an action. This word is used when there is good evidence to suggest that the action is effective, or that, in the opinion of the Panel, it is the best action. Action is advisable.
- **Carry out (perform)** an action. **Do** something. This phrase is used when there is strong evidence that this is the only best action in a certain clinical situation. Action is mandatory.
- **Do not** perform (i.e. avoid) an action. This phrase is used when there is high-level evidence that the action is either ineffective or is harmful to the patient. Action is contraindicated.

Future goals:

- An extended literature search revisiting the topic of female nocturia will be undertaken in collaboration with the Non-neurogenic male LUTS Guidelines Panel.
- An Algorithm for the management of nocturia in both males and females will be presented in the 2018 Urinary Incontinence Guidelines publication.

3. DIAGNOSTIC EVALUATION

3.1 History and physical examination

Taking a careful clinical history is fundamental to the clinical process. Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI. The history should include details of the type, timing and severity of UI, associated voiding and other urinary symptoms. The history should allow UI to be categorised into stress urinary incontinence (SUI), urgency urinary incontinence (UUI) or mixed urinary incontinence (MUI). It should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease. In women, an obstetric and gynaecological history may help to understand the underlying cause and identify factors that may impact on treatment decisions. The patient should also be asked about other ill health and for the details of current medications, as these may impact on symptoms of UI.

Similarly, there is little evidence from clinical trials that carrying out a clinical examination improves care, but wide consensus suggests that it remains an essential part of assessment of people with UI. It should include abdominal examination, to detect an enlarged bladder or other abdominal mass, and perineal and digital examination of the rectum (prostate) and/or vagina. Examination of the perineum in women includes an assessment of oestrogen status and a careful assessment of any associated pelvic organ prolapse (POP). A cough test may reveal SUI if the bladder is sufficiently full while pelvic floor contraction together with urethral mobility can be assessed digitally.

3.2 Patient questionnaires

This section includes symptom scores, symptom questionnaires, scales, indexes, patient reported outcome measures (PROMs) and health-related quality of life (HRQoL) measures. The latter include generic or condition specific measures. Questionnaires should have been validated for the language in which they are being used, and, if used for outcome evaluation, must have been shown to be sensitive to change. The US Food and Drug Administration (FDA) published guidance for industry on patient-reported outcome instruments (questionnaires) in 2009 [8].

3.2.1 Questions

- In patients with UI, can the use of Questionnaires/PROMS differentiate between stress, urgency and mixed incontinence, and does this differentiation impact on quality of life (QoL) after treatment?
- In adults with UI, does assessment using either urinary symptom or QoL questionnaires improve treatment outcome for UI?
- In adults with UI, does assessment of the patient perspective (concerns or expectations) improve patient outcomes, regarding either urinary symptoms or QoL, compared to no patient-reported assessment?

3.2.2 Evidence

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs most of these studies did not include adult patients diagnosed with UI. This limits the extent to which results and conclusions from these studies can be applied in adults with UI. Some questionnaires (QUID, 3IQ) have potential to discriminate UI types in women [9, 10]. In men ICIQ-UI-SF score does not differentiate UI

types [11]. Some questionnaires are responsive to change and may be used to measure outcomes, though evidence on their sensitivity is inconsistent [12-14]. No evidence was found to indicate whether use of QoL or condition specific questionnaires have an impact on outcome of treatment.

Table 1 shows a summary of the ICUD review (2012) with recent additions. Criteria on which questionnaires are assessed include validity, reliability and responsiveness to change.

Table 1: Summary of the ICUD review 2012*.

Recommendation based on expert opinion.

3.3 Voiding diaries

Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of lower urinary tract (LUT) dysfunction, including UI. Voiding diaries are a semi-objective method of quantifying symptoms, such as frequency of UI episodes. They also quantify urodynamic variables, such as voided volume and 24-hour or nocturnal total urine volume. Voiding diaries are also known as micturition time charts, frequency/volume charts and bladder diaries.

Discrepancy between diary recordings and the patient rating of symptoms, e.g. frequency or UI, can be useful in patient counselling. In addition, voided volume measurement can be used to support diagnoses, such as overactive bladder (OAB) or polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials. In patients with severe UI, a voiding diary is unlikely to accurately report 24-hour urine output and so voided volume may be lower than total bladder capacity.

3.3.1 Question

In adults with UI, what is the reliability, diagnostic accuracy and predictive value of a voiding diary compared to patient history or symptom score?

3.3.2 Evidence

Two articles have suggested a consensus has been reached in the terminology used in voiding [16, 17]. However, the terms micturition diary, frequency voiding chart and voiding diary, have been used interchangeably for many years and include information on fluid intake, times of voiding, voided volumes, incontinence episodes, pad usage, degree of urgency and degree of UI recorded for at least 24 hours. When reviewing the evidence all possible terminology has been included.

Two studies have demonstrated the reproducibility of voiding diaries in both men and women [18, 19]. Further studies have demonstrated variability of diary data within a 24-hour period and compared voided volumes recorded in diaries with those recorded by uroflowmetry [20, 21]. Another study found that keeping a voiding diary had a therapeutic benefit [22].

A number of observational studies have demonstrated a close correlation between data obtained from voiding diaries and standard symptom evaluation [23-26].

Summary of evidence	LE
Voiding diaries of three to seven days duration are a reliable tool for the objective measurement of	2b
mean voided volume, day time and night time frequency, and incontinence episode frequency.	
Voiding diaries are sensitive to change and are a reliable measure of outcome.	2b

Recommendations	GR
Ask patients with urinary incontinence to complete a voiding diary.	А
Use a diary duration of between three and seven days.	В

3.4 Urinalysis and urinary tract infection

Reagent strip ('dipstick') urinalysis may indicate urinary tract infection (UTI), proteinuria, haematuria or glycosuria requiring further assessment. Refer to the Urological Infections Guidelines for diagnosis and treatment of UTI [27].

3.4.1 Question

- In adults with UI, what is the diagnostic accuracy of urinalysis to detect UTI?
- In adults with UI does treatment of UTI or asymptomatic bacteriuria cure or improve UI compared to no treatment?

3.4.2 Evidence

Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI in people with UI [28] and should be included, with urine culture when necessary, in the evaluation of all patients with UI. Urinary incontinence may occur during symptomatic UTI [29] and existing UI may worsen during UTI [30]. The rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents [31].

Summary of evidence	LE
Urinalysis negative for nitrite and leucocyte esterase reliably excludes urinary tract infection.	1
Urinary incontinence may be a symptom during urinary tract infection.	3
The presence of a symptomatic urinary tract infection worsens symptoms of urinary incontinence.	3
Elderly nursing home patients with urinary incontinence do not benefit from treatment of asymptomatic	2
bacteriuria.	

Recommendations	GR
Perform urinalysis as a part of the initial assessment of a patient with urinary incontinence.	A*
If a symptomatic urinary tract infection is present with urinary incontinence, reassess the patient after	A*
treatment.	
Do not routinely treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence.	В
	<u>`</u>

* Recommendation based on expert opinion.

3.5 Post-void residual volume

Post-void residual (PVR) volume is the amount of urine that remains in the bladder after voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with UTI, upper urinary tract (UUT) dilatation and renal insufficiency. Both bladder outlet obstruction and detrusor underactivity contribute to the development of PVR. Post-void residual can be measured by catheterisation or ultrasound (US). The prevalence of PVR in patients with UI is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume.

3.5.1 **Question**

In adults with UI, what is the value of measuring PVR?

3.5.2 **Evidence**

Most studies investigating PVR have not included patients with UI. Although some studies have included women with UI and men and women with LUTS, they have also included children and adults with neurogenic UI. In general, the data on PVR can be applied with caution to adults with non-neurogenic UI. The results of studies investigating the best method of measuring PVR [32-37] have led to the consensus that US measurement of PVR is preferable to catheterisation.

In peri- and post-menopausal women without significant LUTS or pelvic organ symptoms, 95% of women had a PVR < 100 mL [38]. In women with UUI, a PVR > 100 mL was found in 10% of cases [39]. Other research has found that a high PVR is associated with POP, voiding symptoms and an absence of SUI [38, 40-42].

In women with SUI, the mean PVR was 39 mL measured by catheterisation and 63 mL measured by US, with 16% of women having a PVR > 100 mL [39].

Summary of evidence

Lower urinary tract symptoms coexisting with Urinary incontinence are associated with a higher rate of 2 post-void residual compared to asymptomatic subjects.

Recommendations	GR
When measuring post-void residual urine volume, use ultrasound.	А
Measure post-void residual in patients with urinary incontinence who have voiding symptoms.	В
Measure post-void residual when assessing patients with complicated urinary incontinence.	С
Post-void residual should be monitored in patients receiving treatments that may cause or worsen	A*
voiding dysfunction, including surgery for stress urinary incontinence.	

* Recommendation based on expert opinion.

LE

3.6 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, in the belief that it may help to provide or confirm diagnosis, predict treatment outcome, or facilitate discussion during counselling. For all these reasons, urodynamics is often performed prior to invasive treatment for UI. These Guidelines will focus on invasive tests, including multichannel cystometry, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry, Valsalva leak point pressure estimation, and retrograde urethral resistance measurement.

3.6.1 **Question**

In adults with UI, what is the reproducibility, diagnostic accuracy and predictive value of urodynamic testing?

3.6.2 Evidence

3.6.2.1 Variability

In common with most physiological tests there is variability in urodynamics results. A number of small studies, assessing same-session repeatability of urodynamic testing, present contradictory findings [43, 44]. Measurement of urethral closure pressure (MUCP) correlates poorly with incontinence severity [45] and there is conflicting evidence about its reproducibility [46, 47]. One method of recording MUCP cannot be compared meaningfully to another [48].

Valsalva leak point pressures are not standardised and there is minimal evidence about reproducibility. Valsalva leak point pressure did not reliably assess incontinence severity in a cohort of women selected for surgical treatment of SUI [49]. The predictive value of the tests, regarding the outcome of treatment, remains unclear. No studies on the reproducibility of ambulatory monitoring were found.

3.6.2.2 Diagnostic accuracy

The diagnostic accuracy of urodynamics is assessed in terms of its correlation with clinical diagnosis of UI and incontinence severity. The problem is that clinical diagnosis and urodynamic findings often do not correlate [50, 51], and normal healthy people may have urodynamic abnormalities.

The diagnostic accuracy of urethral pressure profilometry [45] and 'urethral retro-resistance' is generally poor [52]. Urethral reflectometry may have greater diagnostic accuracy but its clinical role remains unclear [53].

Ambulatory urodynamics may detect unexpected physiological variance from normal more often than conventional cystometry, but the clinical relevance of this is uncertain [54, 55].

3.6.2.3 Question

Does urodynamics influence the outcome of conservative therapy?

3.6.2.4 Evidence

A Cochrane review of seven RCTs showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery. However, there was no evidence that this influence on decision making altered the clinical outcome of treatment [56]. Subanalysis of an RCT comparing fesoterodine to placebo [57, 58] showed no predictive value for treatment response, by the urodynamic diagnosis of detrusor overactivity (DO).

3.6.2.5 Question

Does urodynamics influence the outcome of surgery for urinary incontinence?

3.6.2.6 Evidence

A high-quality RCT (n = 630) compared office evaluation alone to office evaluation and urodynamics in women with clinical demonstrable SUI about to undergo surgery for SUI. Whilst urodynamics changed the clinical diagnosis in 56% of women [59], there was no difference in levels of UI or any secondary outcome at twelve months follow-up after surgery [60]. Another similar study closed with only 59 women included due to recruitment problems, found that the omission of urodynamics was not inferior in the pre-operative work up of SUI [61]. This study was then redesigned so that patients in whom urodynamics were discordant with clinical assessment (n = 109) were randomly allocated to receive either immediate surgery or individually tailored therapy based on urodynamics. In this trial, performing immediate surgery, irrespective of the result of urodynamics, did not result in inferior outcomes [62].

In observational studies there is no consistent correlation between the result of urethral function tests and subsequent success or failure of SUI surgery [24-27]. The same is true for a secondary analysis of an RCT [63].

Augmentation cystoplasty is only performed in patients with a urodynamic diagnosis of DO, so no statement can be made about predictive value for this group [58].

The Panel recognise that it may be valuable to use urodynamic test results to select the optimum surgical procedure but, at the time of this review, there is inconsistent evidence regarding any predictive value that would support this approach.

3.6.2.7 Question

Does urodynamics help to predict complications of surgery for UI?

3.6.2.8 Evidence

There have been no RCTs designed to answer this question.

The presence of pre-operative DO has been associated with post-operative UUI, but did not predict overall treatment failure following mid-urethral sling [63] or following sling surgery or colposuspension.

Whilst low pre-operative flow rate has been shown to correlate with post-operative voiding dysfunction [64, 65], post hoc analysis of two high-quality surgical trials showed that no pre-operative urodynamic parameter had the ability to predict post-operative voiding dysfunction in a selected population of women with low pre-operative PVR [66, 67].

3.6.2.9 Question

Does urodynamics influence the outcome of treatment for post-prostatectomy urinary incontinence in men?

3.6.2.10 Evidence

There are no RCTs examining the clinical usefulness of urodynamics in post-prostatectomy UI. Whilst urodynamics will distinguish causes of incontinence, its ability to predict outcome of surgery for incontinence for these men is uncertain [68, 69].

Summary of evidence	LE
Most urodynamic parameters show variability within the same session and over time, and this limits	3
their clinical usefulness.	
Different techniques of measuring urethral function may have good test-retest reliability, but do not	3
consistently correlate to other urodynamic tests or to the severity of urinary incontinence.	
There is limited evidence that ambulatory urodynamics is more sensitive than conventional	2
urodynamics for diagnosing stress urinary incontinence or detrusor overactivity.	
There may be inconsistency between history and urodynamic results.	3
Preliminary urodynamics can influence the choice of treatment for urinary incontinence, but does not	1a
affect the outcome of conservative therapy or drug therapy for stress urinary incontinence.	
Pre-operative urodynamics in women with uncomplicated, clinically demonstrable stress urinary	1b
incontinence does not improve the outcome of surgery for stress urinary incontinence.	
There is no consistent correlation between the result of urethral function tests and subsequent	3
success or failure of stress urinary incontinence surgery.	
There is no consistent evidence that pre-operative detrusor overactivity is associated with surgical	3
failure of mid-urethral sling in women.	
The presence of pre-operative detrusor overactivity may be associated with persistence of urgency	3
post-operatively.	
There is no evidence that urodynamics predicts the outcomes of treatment for post-prostatectomy	4
incontinence in men.	

Recommendations	GR
(NB: Concerning only neurologically intact adults with urinary incontinence)	
Clinicians carrying out urodynamics in patients with urinary incontinence should:	С
 ensure that the test replicates the patient's symptoms; 	
 interpret results in the context of the clinical problem; 	
check recordings for quality control;	
remember there may be physiological variability within the same individual.	
Advise patients that the results of urodynamics may be useful in discussing treatment options,	С
although there is limited evidence that performing urodynamics will predict the outcome of treatment	
for uncomplicated urinary incontinence.	
Do not routinely carry out urodynamics when offering treatment for uncomplicated urinary	В
incontinence.	
Perform urodynamics if the findings may change the choice of invasive treatment.	В
Do not use urethral pressure profilometry or leak point pressure to grade severity of incontinence or	С
predict the outcome of treatment.	
Urodynamic practitioners should adhere to standards defined by the International Continence Society.	С

3.6.3 Research priority

Does any individual urodynamic test, or combination of tests, influence the choice of treatments or prediction of treatment outcome for UI?

3.7 Pad testing

Measurement of urine loss using an absorbent pad worn over a set period of time or during a protocol of physical exercise can be used to quantify the presence and severity of UI, as well as a patient's response to treatment.

3.7.1 Questions

- In adults with UI, what is the reliability, diagnostic accuracy and predictive value of pad testing?
- In adults with UI, is one type of pad test better than another?

3.7.2 **Evidence**

The clinical usefulness of pad tests for people with UI has been assessed in two systematic reviews [70, 71]. A one-hour pad test using a standardised exercise protocol and a diagnostic threshold of 1.4 g shows good specificity but lower sensitivity for symptoms of SUI and MUI. A 24-hour pad test using a threshold of 4.4 g is more reproducible but is difficult to standardise with variation according to activity level [72]. Pad test with a specific short graded exercise protocol also has diagnostic value but a negative test should be repeated or the degree of provocation increased [73]. The usefulness of pad tests in quantifying severity and predicting outcome of treatment is uncertain [70, 74] although early post-operative testing may predict future continence in men after prostatectomy [75]. Pad test is responsive to change following successful treatment [76]. There is no evidence that one type of pad test is superior to another.

Summary of evidence	LE
A pad test can diagnose urinary incontinence accurately.	2
Standardisation of bladder volume and degree of provocation improves reproducibility.	2
Twenty-four hours is sufficient duration for home-based testing balancing diagnostic accuracy and	2
adherence.	
Change in leaked urine volume on pad tests can be used to measure treatment outcome.	2

Recommendations	GR
Have a standardised duration and activity protocol for pad test.	В
Use a pad test when quantification of urinary incontinence is required.	С
Use repeat pad test after treatment if an objective outcome measure is required.	С

3.7.3 Research priority

- Do the results of pad testing influence the choice of treatments or the prediction of the outcome of treatment for UI?
- Does the amount of physical activity influence the outcome of 24-hour pad testing leading to overestimation of the severity of incontinence?

3.8 Imaging

Imaging improves our understanding of the anatomical and functional abnormalities that may cause UI. In clinical research, imaging is used to understand the relationship between anatomy and function, between conditions of the central nervous system (CNS) or of the lower urinary tract (LUT) and UI, and to investigate the relationship between LUT and pelvic floor imaging and treatment outcome.

Ultrasound and magnetic resonance imaging (MRI) have largely replaced X-ray imaging. Ultrasound is preferred to MRI because of its ability to produce three-dimensional and four-dimensional (dynamic) images at lower cost and wider availability. Studies on LUT imaging in patients with UI often include an evaluation of surgical outcomes, making design and conduct of these trials challenging.

3.8.1 Questions

In adults with UI:

- What is the reliability and accuracy of imaging in the diagnosis of UI?
- Do the results of imaging influence the choice of treatment for UI?
- Do the results of imaging help predict outcome of treatment for UI?
- Do the results of imaging help evaluate outcome of treatments for UI?

3.8.2 Evidence

Many studies have evaluated the imaging of bladder neck mobility by US and MRI, and concluded that UI cannot be identified by a particular pattern of urethrovesical movements [77]. In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with *de novo* SUI [78].

There is a general consensus that MRI provides good global pelvic floor assessment, including POP, defecatory function and integrity of the pelvic floor support [79]. However, there is a large variation in MRI interpretation between observers [80] and little evidence to support its clinical usefulness in the management of UI.

Studies have assessed the use of imaging to assess the mechanism of mid-urethral sling insertion for SUI. One study suggested that mid-urethral sling placement decreased mobility of the mid-urethra but not mobility of the bladder neck [81]. Following mid-urethral sling, a wider gap between symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [82].

Several imaging studies have investigated the relationship between sphincter volume and function in women [83] and between sphincter volume and surgery outcome, in men and women [84, 85]. In patients undergoing radical prostatectomy, longer membranous urethra before and after surgery was associated with a higher rate of continence [86]. However, no imaging test has been shown to predict the outcome of treatment for UI. Imaging of the pelvic floor can identify *levator ani* detachment and hiatus size, although there is little evidence of a relationship to clinical benefit after treatment of UI.

Detrusor wall thickness

As overactive bladder syndrome (OAB) has been linked to detrusor over-activity, it has been hypothesised that frequent detrusor contractions may increase detrusor/bladder wall thickness (DWT/BWT). However, there is no evidence that BWT/DWT imaging improves management of OAB in practice. No consensus exists as to the relationship between OAB and increased BWT/DWT [87].

Summary of evidence	LE
Imaging can reliably be used to measure bladder neck and urethral mobility, although there is no	2b
evidence of clinical benefit for patients with urinary incontinence.	
There is no consistent evidence that bladder (detrusor) wall thickness measurement is useful in the	3
management of urinary incontinence.	

Recommendation

Do not routinely carry out imaging of the upper or lower urinary tract as part of the assessment of urinary incontinence.

3.8.3 Research priority

More research is needed into the relationship between sling position, as determined by imaging, and surgical outcome.

GR

4. DISEASE MANAGEMENT

4.1 Conservative management

In clinical practice, it is the convention that non-surgical therapies are tried first because they usually carry the least risk of harm. They are often used in combination which makes it difficult to determine which components are effective. Containment devices play an important role, especially for individuals who prefer to avoid the risks of interventional treatments, or in whom active treatment is impossible for any reason.

4.1.1 Simple clinical interventions

4.1.1.1 Underlying disease/cognitive impairment

Urinary incontinence, especially in the elderly, has been associated with multiple comorbid conditions including:

- cardiac failure;
- chronic renal failure;
- diabetes;
- chronic obstructive pulmonary disease;
- neurological disease including stroke and multiple sclerosis;
- general cognitive impairment;
- sleep disturbances, e.g. sleep apnoea;
- depression;
- metabolic syndrome.

It is possible that improvement of associated disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients frequently suffer from more than one condition. In addition, interventions may be combined and individualised, making it impossible to decide which alteration in an underlying disease has affected a patient's UI.

4.1.1.1.1 Question

In adults with UI, does improving an associated condition improve UI compared to no correction of that condition?

4.1.1.1.2 Evidence

There is compelling evidence that there is a higher prevalence of UI in women with type 2 diabetes. One study showed no correlation between earlier intensive treatment of type 1 diabetes mellitus and the prevalence of UI in later life vs. conventional treatment [88].

Summary of evidence

•	
There is a lack of evidence that improving any associated condition improves urinary incontinence,	3
with the exception of weight loss (see section 4.1.2.4 Obesity and weight loss).	

Recommendation

Patients with urinary incontinence who have associated conditions, should have appropriate treatment A* for those conditions in line with good medical practice.

* Recommendation based on expert opinion.

4.1.1.2 Adjustment of other (non-incontinence) medication

Although UI is listed as an adverse effect of many drugs in drug compendia, this mainly results from uncontrolled individual patient reports and post-marketing surveillance. Few controlled studies have used the occurrence of UI as a primary outcome, or were powered to assess the occurrence of statistically significant UI, or worsening rates against placebo. In most cases, it is therefore not possible to be sure that a drug causes UI.

In patients with existing UI, particularly the elderly, it may be difficult or impossible to distinguish between the effects of medication, comorbidity or ageing on UI. Although changing drug regimens for underlying disease may be considered as a possible early intervention for UI, there is very little evidence of benefit [50]. There is also a risk that stopping or altering medication may result in more harm than benefit.

4.1.1.2.1 Question

In adults with UI, does adjustment of other (non-incontinence) medication improve UI compared to no change in treatment?

LE

GR

4.1.1.2.2 Evidence

Structured literature review failed to identify any studies addressing whether adjustment of specific medications could alter existing symptoms of UI. Also, there is little evidence relating to the occurrence or worsening of UI in relation to prescription of any specific drugs.

Summary of evidence	LE
There is very little evidence that alteration of non-incontinence medication can cure or improve	3
symptoms of urinary incontinence.	

Recommendations	GR
Take a drug history from all patients with urinary incontinence.	А
Review any new medication associated with the development or worsening of urinary incontinence.	С

4.1.1.3 Constipation

Several studies have shown strong associations between constipation and UI. Constipation can be improved by behavioural, physical and medical treatments.

4.1.1.3.1 Question

Does treatment for constipation improve UI?

4.1.1.3.2 Evidence

Two, large, cross-sectional population-based studies [89, 90] and two longitudinal studies [91, 92] showed that constipation was a risk factor for LUTS. An observational study comparing women with UI and women with pelvic organ prolapse (POP) to controls found that a history of constipation was associated with both prolapse and UI [93]. One RCT found that a multimodal intervention in elderly patients, involving assisted toileting, fluid intake, etc., reduced the occurrence of UI and constipation, while behavioural therapy appeared to improve both [94].

In conclusion, constipation appears to be associated with UI. However, there is no evidence to show whether or not treating constipation improves UI, although both constipation and UI appear to be improved by certain behavioural interventions.

Summary of evidence	LE
There is a consistent association between a history of constipation and the development of urinary	3
incontinence and pelvic organ prolapse.	
There is no consistent evidence in adults that treatment of constipation alone improves urinary	4
incontinence.	

Recommendation	GR
Adults with urinary incontinence who also suffer from constipation should be given advice about	С
bowel management in line with good medical practice.	

4.1.1.3.3 Research priority

Does the normalisation of bowel habit improve UI in patients who are constipated?

4.1.1.4 Containment

Containment is important for people with UI when active treatment does not cure the problem, or when it is not available or not possible. Some individuals may prefer containment rather than undergo active treatment with its associated risks. This includes the use of absorbent pads, urinary catheters, external collection devices, penile clamps for men and intravaginal devices for women. Studies of catheter use are not specific to patients with non-neurogenic UI. Detailed literature summaries can be found in the current ICUD monograph [1] and in European Association of Urological Nurses guidance documents [95-97]. A useful resource for health care professionals and patients can be found at: www.continenceproductadvisor.org.

4.1.1.4.1 Question

For adults with UI, is one type of containment device better than another?

4.1.1.4.2 Evidence

One RCT involving elderly women in care comparing management with pads to indwelling urethral catheter found no difference in dependency level or skin integrity score at six months [98]. Use of an external sheath was compared with indwelling catheterisation over 30 days in an RCT involving elderly men resident in hospital [99]; there were no differences in bacteriuria or symptomatic UTI but the sheath was more comfortable. A short-term (two weeks) crossover RCT in men with UI found that disease specific QoL was better when using an external sheath and more men preferred it, compared to pads [100].

4.1.1.4.3 Question

For men or women with UI, is one type of pad better than another?

4.1.1.4.4 Evidence

A systematic review of six RCTs comparing different types of pads found that pads filled with superabsorbent material were better than standard pads, whilst evidence that disposable pads were better than washable pads was inconsistent [101]. For men with light UI, a randomised crossover trial found that a leaf-shaped type of pad was preferred to rectangular pads [102]. A series of three crossover RCTs examined performance of different pad designs for differing populations [103]. For women with light UI, disposable insert pads (within washable pouch pants) were most effective. In adults with moderate/severe incontinence, disposable pull-up pants were more effective for women, whilst for men disposable diapers were more effective during the day and washable diapers at night.

4.1.1.4.5 Question

For men or women with UI, is one type of catheter or external collection device better than another?

4.1.1.4.6 Evidence

A Cochrane review summarised three RCTs comparing different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [104]. A systematic review of non-randomised studies found no differences in UTI outcome or UUT changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [105]. For people using intermittent catheterisation, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [106]. However, there is recent evidence from a narrative review suggesting that in certain populations using single-use catheters may reduce urethral trauma and UTI [107]. A Cochrane review summarising five trials comparing washout policies in adults with indwelling urinary catheters found inconsistent evidence of benefit [108].

A further Cochrane review summarising eight trials testing whether antibiotic prophylaxis was beneficial for adults using intermittent or indwelling catheterisation found it reduced incidence of symptomatic UTI but possible harms were not assessed [109].

4.1.1.4.7 Question

For men and women with UI, are external pressure devices more effective than standard treatment and is one device better than another?

4.1.1.4.8 Evidence

A crossover RCT in twelve men with post-prostatectomy incontinence found a hinge-type penile clamp to be more effective than circular clamps for control of UI and that the hinge-type penile clamp was preferred by participants, although it reduced penile blood flow [110].

A Cochrane review summarised seven trials comparing mechanical devices in women with UI finding limited evidence that SUI was reduced by intravaginal devices, no evidence on the effectiveness of intra-urethral devices, and that there was no difference in control of UIns between intravaginal and intra-urethral devices [111]. There was no difference in outcome at twelve months in women with SUI between vaginal pessary alone; pelvic floor muscle training (PFMT) alone; and vaginal pessary + PFMT, although vaginal pessary was inferior to PFMT at three months for bother from UI.

Summary of evidence	LE
Pads are effective in containing urine.	1b
Hinge-type penile clamps are more effective than circular clamps to control stress urinary incontinence	2a
in men.	
Vaginal devices may improve stress urinary incontinence in women in selective groups.	2a

Recommendations	GR
Ensure that adults with urinary incontinence and/or their carers are informed regarding available	A*
treatment options before deciding on containment alone.	
Suggest use of disposable insert pads for women and men with light urinary incontinence.	A*
In collaboration with other healthcare professionals with expertise in urinary incontinence, help	A*
adults with moderate/severe urinary incontinence to select the individually best containment regimen	
considering pads, external devices and catheters, balancing benefits and harms.	
Choice of pad, from the wide variety of different absorbent materials and designs available, should	В
be made with consideration of the individual patient's circumstance, degree of incontinence and	
preference.	

* Recommendation based on expert opinion.

4.1.1.4.9 Research priority

To develop methods for assessing the best method of containment for individual adults with UI.

4.1.2 Lifestyle interventions

Examples of lifestyle factors that may be associated with incontinence include obesity, smoking, level of physical activity and diet. Modification of these factors may improve UI.

4.1.2.1 Caffeine reduction

Many drinks contain caffeine, particularly tea, coffee and cola. Anecdotal evidence of urinary symptoms being aggravated by excessive caffeine intake has focused attention on whether caffeine reduction may improve UI. However, a cross-sectional population survey found no statistical association between caffeine intake and UI [112]. Lack of knowledge about the caffeine content of different drinks has made the role of caffeine reduction in alleviating UI difficult to assess.

4.1.2.1.1 Question

In adults with UI, does caffeine reduction improve UI or QoL compared to no caffeine reduction?

4.1.2.1.2 Evidence

Four studies were found on the effect of caffeine reduction on UI [113-116]. They were of moderate quality and the results were inconsistent. The studies were mainly in women, so results can only be cautiously generalised to men [114, 115]. One RCT showed that reducing caffeine intake as an adjunct to behavioural therapy resulted in reduced urgency but not reduced UI compared to behavioural therapy alone [114]. Another RCT found that reducing caffeine had no benefit for UI [115]. A further interventional study in the elderly showed borderline significance for the benefit of reducing caffeine intake on UI [116]. In a large prospective cohort study there was no evidence that caffeine reduction reduced the risk of progression of UI over two years [117].

Summary of evidence	LE
Reduction of caffeine intake does not improve urinary incontinence.	2
Reduction in caffeine intake may improve symptoms of urgency and frequency.	2

4.1.2.2 Physical exercise

Regular physical activity may strengthen the pelvic floor musculature and possibly decrease the risk of developing UI, especially SUI. However, it is also possible that heavy physical exercise may aggravate UI.

4.1.2.2.1 Question

Does physical exercise cause, improve or exacerbate UI in adults?

4.1.2.2.2 Evidence

The association between exercise and UI is unclear. Four studies [112, 118-120] in differing populations concluded that strenuous physical exercise increases the risk of SUI during periods of physical activity. There is also consistent evidence that physically active females and elite athletes experience higher levels of SUI than control populations [121-126]. On the other hand, the presence of UI may prevent women from taking exercise [127]. There is no evidence that strenuous exercise predisposes athletes to the development of SUI later in life [128]. Lower levels of UI have been observed in cohorts of women who undertake moderate exercise, but it remains unclear whether taking exercise can prevent development of UI [129, 130].

The elderly

Three RCTs in the elderly confirmed that exercise, as a component of a multidimensional regime including PFMT and weight loss, was effective in improving UI in women. It is not clear which component of such a scheme is most important [94, 131, 132].

Summary of evidence	LE
Female athletes may experience urinary incontinence during intense physical activity but not during	3
common activities.	
Strenuous physical activity does not predispose for women to urinary incontinence later in life.	3
Moderate exercise is associated with lower rates of urinary incontinence in middle-aged or older	2b
women.	

4.1.2.3 Fluid intake

Modification of fluid intake, particularly restriction, is a strategy commonly used by people with UI to relieve symptoms. Advice on fluid intake given by healthcare professionals should be based on 24-hour fluid intake and urine output measurements. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that low or high 24-hour urine output should be investigated.

4.1.2.3.1 Question

In adults with UI, what is the effect of modifying fluid intake compared to not modifying fluid intake on symptoms and QoL?

4.1.2.3.2 Evidence

The few RCTs [115, 133, 134] provide inconsistent evidence. In most studies, the instructions for fluid intake were individualised and it is difficult to assess participant adherence to protocol. All available studies were in women. An RCT [134] showed that a reduction in fluid intake by 25% improved symptoms in patients with OAB but not UI. Personalised fluid advice compared to generic advice made no difference to continence outcomes in people receiving antimuscarinics for OAB, according to an RCT comparing drug therapy alone to drug therapy with behavioural advice [135].

Summary of evidence	LE
There is conflicting evidence on whether fluid modification improves urinary incontinence.	2

4.1.2.4 Obesity and weight loss

Being overweight or obese has been identified as a risk factor for UI in many epidemiological studies [136, 137]. There is evidence that the prevalence of both UUI and SUI increases proportionately with rising body mass index [138]. The proportion of patients who undergo surgery for incontinence who are overweight or obese is higher than that of the general population [139].

4.1.2.4.1 Question

In adults with UI, does weight loss lead to an improvement in symptoms of UI or QoL?

4.1.2.4.2 Evidence

All the available evidence relates to women. Three systematic reviews plus two large RCTs concluded that weight loss was beneficial in improving UI [136, 137, 140]. Five further RCTs reported a similar beneficial effect on incontinence following surgical weight reduction programmes [141-144]. Two large studies in women with diabetes, for whom weight loss was the main lifestyle intervention, showed UI did not improve but there was a lower subsequent incidence of UI among those who lost weight [141, 145]. There have been other cohort studies and case-control studies suggesting similar effects, including surgery for the morbidly obese [146-150].

Summary of evidence	LE
Obesity is a risk factor for urinary incontinence in women.	1b
Non-surgical weight loss in overweight and obese women improves urinary incontinence.	1a
Surgical weight loss improves urinary incontinence in obese women.	1b
Weight loss in obese women improves urinary incontinence.	1b
Weight loss in obese adults with diabetes mellitus reduces the risk of developing urinary incontinence.	1b

4.1.2.5 Smoking

Smoking cessation is now a generalised public health measure and has been shown to be weakly associated with improving urgency frequency and UI [112, 151].

4.1.2.5.1 Question

In adults with UI, does smoking cessation improve patient outcomes regarding either urinary symptoms or QoL compared to continued smoking?

4.1.2.5.2 Evidence

The effect of smoking cessation on UI was described as uncertain in a NIHR review [152].

Summary of evidence	LE
There is no evidence that smoking cessation will improve the symptoms of urinary incontinence.	4

4.1.2.6 Recommendations for lifestyle interventions

Recommendations	GR
Encourage obese women with urinary incontinence to lose weight and maintain weight loss.	А
Advise adults with urinary incontinence that reducing caffeine intake may improve symptoms of urgency and frequency but not incontinence.	В
Patients with abnormally high or abnormally low fluid intake should be advised to modify their fluid intake appropriately in line with good medical practice.	С
Counsel female athletes experiencing urinary incontinence with intense physical activity that it will not predispose them to urinary incontinence in later life.	С
Patients with urinary incontinence who smoke should be given smoking cessation advice in line with good medical practice.	A

4.1.2.7 Research priority

Which lifestyle modifications are effective for the cure or sustained improvement of UI?

4.1.3 Behavioural and Physical therapies

Terminology relating to behavioural and physical therapies remains confusing because of the wide variety of ways in which treatment regimens and combinations of treatments have been delivered in different studies [153]. The terms are used to encompass all treatments which require a form of self-motivated personal retraining by the patient and also include techniques which are used to augment this effect.

Approaches include bladder training (BT) and pelvic floor muscle training (PFMT), but terms such as bladder drill, bladder discipline and bladder re-education and behaviour modification are also used. Almost always in clinical practice, these will be introduced as part of a package of care including lifestyle changes, patient education and possibly some cognitive therapy as well. The extent to which individual therapists motivate, supervise and monitor these interventions is likely to vary but it is recognised that these influences are important components of the whole treatment package.

4.1.3.1 Prompted voiding

The term 'prompted voiding' implies that carers, rather than the patient, initiate the decision to void and this applies largely to an assisted care setting.

Two systematic reviews (nine RCTs) [154, 155] confirmed a positive effect on continence outcomes for prompted voiding in comparison to standard care [155]. Timed voiding is defined as fixed, pre-determined, time intervals between toileting, applicable for those with or without cognitive impairment. A Cochrane review of timed voiding reviewed two RCTs, finding inconsistent improvement in continence compared with standard care in cognitively impaired adults [156].

4.1.3.2 Bladder Training

Bladder training (also referred to in the past as bladder drill, bladder discipline, bladder re-education, bladder retraining): A programme of patient education along with a scheduled voiding regimen with gradually adjusted voiding intervals. Specific goals are to correct faulty habit patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes and restore

patient confidence in controlling bladder function. The ideal form or intensity of a BT programme for UI is unclear. It is also unclear whether or not BT can prevent the development of UI.

4.1.3.2.1 Questions

In adults with UI:

- Is BT better than no treatment for cure or improvement of UI?
- Is BT better than other conservative treatments for cure or improvement of UI?
- Does BT, as an adjunct to other conservative treatments, cure or improve UI?
- Are the benefits of BT durable in the longer term?
- Are there any patient groups for whom BT is more effective?

4.1.3.2.2 Evidence

There have been three systematic reviews on the effect of BT compared to standard care [50, 152, 157] confirming that BT is more effective than no treatment in improving UUI. The addition of BT to anticholinergic therapy did not improve UI compared to antimuscarinics alone but it did improve frequency and nocturia [158].

This review identified seven RCTs in which BT was compared to drug therapy alone and showed only a benefit for oxybutynin in cure and improvement of UI [158].

Bladder training alone is inferior to a high-intensity programme of PFMT to improve SUI in elderly women [159]. Bladder training is better than intravaginal pessaries to control SUI, although the improvement may only be short term. Whatever the method of training used, any benefit of BT on UI is likely to be of short duration unless the BT programme is practised repeatedly. No adverse events have been reported with BT. Biofeedback combined with BT increased continence rates and improved MUI in two RCTs [157].

Bladder training is effective for improvement of urinary incontinence in women. 1b The effectiveness of bladder training diminishes after the treatment has ceased. 2 The comparative benefit of bladder training and drugs for the improvement of urgency urinary incontinence remains uncertain. 2 The combination of bladder training with antimuscarinic drugs does not result in greater improvement of urinary incontinence but may improve frequency and nocturia. 1b	Summary of evidence	LE
The effectiveness of bladder training diminishes after the treatment has ceased. 2 The comparative benefit of bladder training and drugs for the improvement of urgency urinary incontinence remains uncertain. 2 The combination of bladder training with antimuscarinic drugs does not result in greater improvement of urgency urinary incontinence but may improve frequency and nocturia. 1b	Bladder training is effective for improvement of urinary incontinence in women.	1b

For recommendations see section 4.1.3.5.

4.1.3.3 Pelvic floor muscle training (PFMT)

Pelvic floor muscle training is used to improve function of the pelvic floor, improving urethral stability. There is some evidence that improving pelvic floor function may inhibit bladder contraction in patients with OAB [160]. Pelvic floor muscle training may be used to prevent UI, e.g. in childbearing women before birth, in men about to undergo radical prostatectomy, or as part of a planned recovery programme after childbirth or surgery. Most often, PFMT is used to treat existing UI, and may be augmented with biofeedback (using visual, tactile or auditory stimuli), surface electrical stimulation or vaginal cones.

4.1.3.3.1 Question

In adult men and women suffering from UI, does treatment with PFMT, given either alone or augmented with biofeedback, electrical stimulation or vaginal cones, improve or cure UI or improve QoL, compared to no treatment, sham treatment or other conservative treatments, e.g. bladder training, electrical stimulation or vaginal cones?

4.1.3.3.2 Evidence

In a recent UK Health Technology Appraisal (HTA), the role of PFMT in the care of women with SUI was analysed in a direct comparison of treatments using a mixed treatment comparison model, which compared different 'packages' of care [152]. This extensive meta-analysis reviewed data from 37 interventions and 68 direct comparisons, while the mixed treatment comparisons examined combinations of fourteen different types of intervention from 55 separate trials. The mixed treatment comparison used both indirect and direct comparisons and may provide more accurate estimates of effect. Where relevant, the Health Technology Appraisal has influenced the evidence and recommendations in these Guidelines. The Agency for Healthcare

Research and Quality (AHRQ) review of nonsurgical treatment of UI in adult women also included indirect comparison methods as well as conventional meta-analysis [157].

4.1.3.3.3 Efficacy of PFMT in SUI, UUI and MUI in women

This question has been addressed by several systematic reviews [152, 157, 161], all report inconsistency between studies because of poor reporting of technique and different outcome measures. Meta-analysis showed that PFMT was effective for cure or improvement of incontinence, and improvement in QoL. The effect applies in women with SUI, UUI and MUI though the effect in MUI is lower than in women with pure SUI. A Cochrane review comparing different approaches to delivery of PFMT (21 RCTs) concluded that increased intensity of delivery of the therapy improves response and that there is no consistent difference between group therapy and individualised treatment sessions [162]. No other consistent differences between techniques were found.

With regard to the durability of PFMT, another RCT reported fifteen-year follow-up outcomes of an earlier RCT, showing that long-term adherence to treatment was poor and half of patients had progressed to surgery [163]. Numerous systematic reviews have addressed the question of whether the effects of PFMT and BT are additive [152, 157, 164]. These reviews are confounded by differences in patient selection and have arrived at conflicting conclusions leaving uncertainty about the extent to which one treatment may augment the other. Similarly, there remains uncertainty about the additional value of biofeedback with systematic reviews reaching differing conclusions [157, 164].

Comparison of PFMT to other treatments was extensively reviewed by both AHRQ and the 2010 UK HTA [152, 157], which considered additional non-randomised data as part of a mixed treatment comparison. The UK HTA resulted in a number of different findings from those based solely on direct comparisons. In conclusion, the HTA, using a revised methodology, supporting the general principle that greater efficacy was achieved by adding together different types of treatment and by increasing intensity.

Efficacy of PFMT in childbearing women

Two systematic reviews [165, 166] reviewed RCTs in pregnant or postpartum women, which included PFMT in one arm of the trial. Treatment of UI with PFMT in the postpartum period increased the chances of continence at 12 months' postpartum.

4.1.3.3.4 PFMT in the elderly

The effect of PFMT in women with SUI does not seem to decrease with increased age: in trials with older women with SUI it appeared both primary and secondary outcome measures were comparable to those in trials focused on younger women [131, 159, 167].

4.1.3.3.5 PFMT and Radical prostatectomy

A 2015 Cochrane review concluded that there was no overall benefit at twelve months post-surgery for men who received post-operative PFMT for the treatment of post-prostatectomy urinary incontinence (PPI) and that the benefits of conservative treatment of PPI remain uncertain [168]. A meta-analysis within this review showed that a greater proportion of men were dry from between three and twelve months suggesting that PFMT may speed recovery of continence. A subsequent study adds to this evidence [169].

Two additional RCTs have shown that written instructions alone offer similar levels of improvement to supervised PFMT [170, 171]. One RCT found that PFMT was helpful in men who had been incontinent for at least one year after prostatectomy, and who had had no previous therapy [172].

One RCT compared PFMT to no treatment in men undergoing TURP. There was no demonstrable difference in the incidence of post-operative incontinence up to twelve months [173].

Summary of evidence	LE
Pelvic floor muscle training (PFMT) for women with urinary incontinence	
Pelvic floor muscle training is better than no treatment for improving urinary incontinence and QoL in	1
women with stress urinary incontinence and mixed urinary incontinence.	
Higher-intensity, supervised treatment regimes, and the addition of biofeedback, confer greater benefit	1
in women receiving PFMT.	
Short-term benefits of intensive PFMT are not maintained at fifteen-year follow-up.	2
Pelvic floor muscle training commencing in the early postpartum period improves urinary incontinence	1
in women for up to twelve months.	

Pelvic floor muscle training for post-prostatectomy urinary incontinence				
Pelvic floor muscle training appears to speed the recovery of continence following radical	1b			
prostatectomy.				
Pelvic floor muscle training does not cure urinary incontinence in men post radical prostatectomy or	1b			
transurethral prostatectomy.				
There is conflicting evidence on whether the addition of bladder training, electrical stimulation or	2			
biofeedback increases the effectiveness of PFMT alone.				
Pre-operative PFMT does not confer additional benefit to men undergoing radical prostatectomy.	1b			

For recommendations see section 4.1.3.5.

4.1.3.3.6 Electrical stimulation

The details and methods of delivery of electrical stimulation vary considerably. Electrical stimulation (ES) of the pelvic floor can also be combined with other forms of conservative therapy, e.g. PFMT and biofeedback. Electrical stimulation is often used to assist women who cannot initiate contractions to identify their pelvic floor muscles. Electrical stimulation is also used in patients with OAB and UUI, for detrusor inhibition. It has been suggested that ES probably targets the pelvic floor directly in SUI and the detrusor muscle or pelvic floor muscle or afferent innervation in UUI.

4.1.3.3.7 Question

In adults with UI, does treatment with ES improve or cure symptoms of UI or QoL compared to no/sham treatment or antimuscarinics?

4.1.3.3.8 Evidence

Most evidence on ES refers to women with SUI. The topic has been included in two HTAs [152, 157] and three systematic reviews [50, 174, 175]. The reviews include analysis of fifteen trials and use different comparison methods, but differ in their assessment of whether ES is more effective than sham stimulation and whether ES adds to the benefit of PFMT alone. Studies were considered to be of generally low quality, with a variety of stimulation parameters, treatment regimens and outcome parameters [168].

A subanalysis in a systematic review on one small low quality RCT in which ES had been compared to oxybutynin and PFMT in patients with UI, showed no difference in incontinence outcomes [176].

A Cochrane review of ES in men with UI (six RCTs) concluded that there was some evidence that electrical stimulation enhanced the effect of PFMT in the short-term but not after six months. Electrical Stimulation was also more effective than sham stimulation at six, but not twelve months. There were, however, more adverse effects (pain or discomfort) with ES [177].

Electromagnetic stimulation has been promoted as treatment for UI but weak evidence of the short-term and long-term effects has been found in systematic reviews [178, 179].

Summary of evidence	LE
In adults with urinary incontinence, electrical stimulation may improve urinary incontinence compared	2
to sham treatment and antimuscarinics.	
Electrical stimulation may add benefit to pelvic floor muscle training in the short-term.	2

For recommendations see section 4.1.3.5.

4.1.3.4 Posterior tibial nerve stimulation

Electrical stimulation of the posterior tibial nerve (PTNS) delivers electrical stimuli to the sacral micturition centre via the S2-S4 sacral nerve plexus. Stimulation is done percutaneously with a fine, 34-G, needle, inserted just above the medial aspect of the ankle (P-PTNS). Transcutaneous stimulation is also available (T-PTNS). Treatment cycles typically consist of twelve weekly treatments of 30 minutes.

4.1.3.4.1 Question

In adults suffering from UUI, what is the clinical effectiveness of PTNS compared to sham treatment or alternative treatment such as antimuscarinic drugs?

4.1.3.4.2 Evidence *P-PTNS*

The reviewed studies included two twelve-week RCTs of PTNS against sham treatment [180, 181], one

comparing PTNS to tolterodine, and a three-year extension trial utilising a maintenance protocol in patients with UUI [182, 183]. The results of studies of PTNS in women with refractory UUI are consistent. Considered together, these results suggest that PTNS improves UUI in women who have had no benefit from antimuscarinic therapy or who are not able to tolerate these drugs. However, there is no evidence that PTNS cures UUI in women. In addition, PTNS is no more effective than tolterodine for improvement of UUI in women. In men there is insufficient evidence to reach a conclusion about efficacy.

T-PTNS

A small RCT compared transcutaneous PTNS plus standard treatment (PFMT and BT) with PFMT and BT alone in older women [184]. Women in the T-TPNS group were more likely to achieve improvement at the end of therapy.

Summary of evidence	LE
Percutaneous posterior tibial nerve stimulation (P-PTNS) appears effective for improvement of urgency	2b
urinary incontinence in women who have had no benefit from antimuscarinic medication.	
A maintenance programme of P-PTNS has been shown to be effective up to three years.	1b
Percutaneous Posterior tibial nerve stimulation has comparable effectiveness to tolterodine for	1b
improvement of urgency urinary incontinence in women.	
No serious adverse events have been reported for P-PTNS in urgency urinary incontinence.	3
There is limited evidence for effectiveness of transcutaneous posterior tibial nerve stimulation (PTNS).	2a
There is no evidence that P-PTNS cures urinary incontinence.	2b

4.1.3.5 Recommendations for behavioural and physical therapies

Recommendations	GR
Offer bladder training as a first-line therapy to adults with urgency urinary incontinence or mixed	А
urinary incontinence.	
Offer prompted voiding for adults with incontinence who are cognitively impaired.	А
Offer supervised intensive pelvic floor muscle training (PFMT), lasting at least three months, as a first-	А
line therapy to women with stress urinary incontinence or mixed urinary incontinence.	
Pelvic floor muscle training programmes should be as intensive as possible.	В
Offer PFMT to elderly women with urinary incontinence.	А
Offer PFMT to post-natal women with urinary incontinence.	А
Consider using biofeedback as an adjunct in women with stress urinary incontinence.	В
Offer PFMT to men undergoing radical prostatectomy to speed recovery of incontinence.	А
Do not offer electrical stimulation with surface electrodes (skin, vaginal, anal) alone for the treatment of	А
stress urinary incontinence.	
Consider offering electrical stimulation as an adjunct to behavioural therapy in patients with urgency	В
urinary incontinence.	
Do not offer magnetic stimulation for the treatment of incontinence or overactive bladder in adult	В
women.	
Offer, if available, PTNS as an option for improvement of urgency urinary incontinence in women who	В
have not benefitted from antimuscarinic medication.	
Support other healthcare professionals in use of rehabilitation programmes including prompted	А
voiding for elderly care-dependent people with urinary incontinence.	

4.1.4 Conservative therapy in mixed urinary incontinence

About one-third of women with UI have MUI with symptoms of both SUI and UUI, and this becomes more common with increasing age. In terms of evidence base, many studies include patients with MUI, but it is rare for these studies to provide a separate analysis of patients with MUI.

4.1.4.1 Question

In adults with MUI, is the outcome of conservative therapy different to that obtained with the same treatment in patients with either pure SUI or pure UUI?

4.1.4.2 Evidence

No specific systematic reviews were found that addressed the above question. However, a Cochrane report on

pelvic floor muscle training (PFMT) [161] concluded that training was less likely to result in a cure in patients with MUI than in patients with pure SUI, though it is not clear from the report how this conclusion was reached.

A small RCT (n = 71) compared delivery of PFMT, with or without an instructive audiotape. It showed equal efficacy for different types of UI [185].

Following a RCT of PFMT, a review of 88 women available for follow-up at five years found that outcomes were less satisfactory in women with MUI than in women with pure SUI [186].

Summary of evidence	LE
Pelvic floor muscle training appears less effective for mixed urinary incontinence than for stress urinary	2
incontinence alone.	
Electrical stimulation is equally effective for mixed urinary incontinence and stress urinary	1b
incontinence.	

4.1.4.3 Recommendations conservative therapy in mixed urinary incontinence

Recommendations	GR
Treat the most bothersome symptom first in patients with mixed urinary incontinence.	С
Warn patients with mixed urinary incontinence that the chance of success of pelvic floor muscle	В
training is lower than for stress urinary incontinence alone.	

4.2 Pharmacological management

4.2.1 Antimuscarinic drugs

Antimuscarinic (anticholinergic) drugs are currently the mainstay of treatment for UUI. They differ in their pharmacological profiles, e.g. muscarinic receptor affinity and other modes of action, in their pharmacokinetic properties, e.g. lipid solubility and half-life, and in their formulation.

The evaluation of cure or improvement of UI is made harder by the lack of a standard definition of improvement and the failure to use cure as a primary outcome. In general, systematic reviews note that the overall treatment effect of drugs is usually small but larger than placebo.

Dry mouth is the commonest side effect, though constipation, blurred vision, fatigue and cognitive dysfunction may occur [157].

The immediate release (IR) formulation of oxybutynin is the archetype drug in the treatment of UUI. Oxybutynin IR provides maximum dosage flexibility, including an off-label 'on-demand' use. Immediate-release drugs have a greater risk of side effects than extended release (ER) formulations because of differing pharmacokinetics. A transdermal delivery system (TDS) and gel developed for oxybutynin gives a further alternative formulation.

4.2.1.1 Question

In adults with UUI, are antimuscarinic drugs better than placebo for improvement or cure of UUI and for the risk of adverse effects?

4.2.1.2 Evidence

Seven systematic reviews of individual antimuscarinic drugs vs. placebo were reviewed for this section [157, 187-192] as well as studies published since these reviews up until April 2016. Most studies included patients with a mean age of 55-60 years. Both female and male subjects were included in different studies but results cannot be generalised across sexes. Only short-term rates for improvement or cure of UUI are reported. The evidence reviewed was consistent, indicating that ER and IR formulations of antimuscarinics offer clinically significant short-term cure and improvement rates for UUI compared to placebo. On balance, IR formulations tend to be associated with more side effects compared to ER formulations [191].

Cure of UI was deemed to be the most important outcome measure. Risk of adverse events was best represented by withdrawal from a trial because of adverse events, although this does not reflect practice. Table 2 shows a summary of the findings from a systematic review [157]. In summary, every drug where cure of UI was available shows superiority compared to placebo in achieving UI, but the absolute size of effect is small.

Drug	No. of studies	Patients	Relative risk	Number needed to treat
			(95% CI) (of	(95% CI) (to achieve one
			curing UI)	cure of UI)
Cure of incontinence				
Fesoterodine	2	2,465	1.3 (1.1-1.5)	8 (5-17)
Oxybutynin (includes IR)	4	992	1.7 (1.3-2.1)	9 (6-16)
Propiverine (includes IR)	2	691	1.4 (1.2-1.7)	6 (4-12)
Solifenacin	5	6,304	1.5 (1.4-1.6)	9 (6-17)
Tolterodine (includes IR)	4	3,404	1.2 (1.1-1.4)	12 (8-25)
Trospium (includes IR)	4	2,677	1.7 (1.5-2.0)	9 (7-12)
Discontinuation due to ad	verse events			
			Relative Risk	NNT (95% CI) (of one
			(95% CI) (of	discontinuation)
			discontinuation)	
Darifenacin	7	3,138	1.2 (0.8-1.8)	
Fesoterodine	4	4,433	2.0 (1.3-3.1)	33 (18-102)
Oxybutynin (includes IR)	5	1,483	1.7 (1.1-2.5)	16 (8-86)
Propiverine (includes IR)	2	1,401	2.6 (1.4-5)	29 (16-77)
Solifenacin	7	9,080	1.3 (1.1-1.7)	78 (39-823)
Tolterodine (includes IR)	10	4,466	1.0 (0.6-1.7)	
Trospium (includes IR)	6	3,936	1.5 (1.1-1.9)	56 (30-228)

Table 2: Summary of cure rates and discontinuation rates of antimuscarinic drugs from RCTs which reported these outcomes [157]

4.2.1.2.1 Darifenacin

The cure rates for darifenacin were not included in the AHRQ review. Continence rates were 29-33% for darifenacin compared to 17-18% for placebo [157].

4.2.1.2.2 Transcutaneous oxybutynin

Transdermal oxybutynin has shown a significant improvement in the number of incontinence episodes and micturitions per day vs. placebo and other oral formulations but continence was not reported as an outcome [157].

Oxybutynin topical gel was superior to placebo for improvement of UUI with a higher proportion of participants being cured [157, 193].

There is limited evidence that patients who do not respond to a first-line antimuscarinic treatment may respond to a higher dose or a different antimuscarinic agent [194, 195].

4.2.2 Comparison of antimuscarinic agents

Head-to-head comparison trials of the efficacy and side effects of different antimuscarinic agents are of interest for decision making in practice.

4.2.2.1 Question

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI, and/or a greater improvement in QoL, and/or a lesser likelihood of adverse effects compared to an alternative antimuscarinic drug?

4.2.2.2 Evidence

There are over 40 RCTs and eight systematic reviews [157, 176, 187, 189, 192, 196-198]. Nearly all the primary studies were industry sponsored. Upward dose titration is often included in the protocol for the experimental arm, but not for the comparator arm.

In general, these studies have been designed for regulatory approval. They have short treatment durations (twelve weeks) and a primary outcome of a change in OAB symptoms rather than a cure of, or an improvement in, UUI, which were generally analysed as secondary outcomes. The clinical utility of these trials in real life practice is questionable. Most trials were of low or moderate quality [189]. The 2012 Agency for Healthcare Research and Quality (AHRQ) review included a specific section addressing comparisons of antimuscarinic drugs (Table 2).

Fesoterodine

Results of an RCT of fesoterodine 4 versus 8 mg suggested a larger therapeutic effect on UUI with the higher dose but with more adverse events [194].

No antimuscarinic agent improved QoL more than another agent [189]. Dry mouth is the most prevalent adverse effect. Good evidence indicates that, in general, higher doses of any drug are likely to be associated with higher rates of adverse events. Also, ER formulations of short-acting drugs and longer-acting drugs are generally associated with lower rates of dry mouth than IR preparations [189, 196]. Oxybutynin IR showed higher rates of dry mouth than tolterodine IR and trospium IR, but lower rates of dry mouth than darifenacin, 15 mg daily [189, 196]. Overall, oxybutynin ER has higher rates of dry mouth than tolterodine ER, although the incidence of moderate or severe dry mouth were similar. Transdermal oxybutynin had a lower rate of dry mouth than oxybutynin IR and tolterodine ER, but had an overall higher rate of withdrawal due to an adverse skin reaction [189]. Solifenacin, 10 mg daily, had higher rates of dry mouth than tolterodine ER [189]. Fesoterodine, 8 mg daily, had a higher rate of dry mouth than tolterodine ER [189]. Fesoterodine, 8 mg daily, had a higher rate of dry mouth than tolterodine ER [189]. Similar discontinuation rates were observed, irrespective of differences in the occurrence of dry mouth (doses have been given were the evidence relates to a specific dose level typically from trials with a dose escalation element).

Summary of evidence	LE	
There is limited evidence that one antimuscarinic drug is superior to an alternative antimuscarinic drug	1b	
for cure or improvement of urgency urinary incontinence.		
Higher doses of antimuscarinic drugs are more effective to cure or improve urgency urinary	1b	
incontinence, but with a higher risk of side effects.		
Once daily (extended release) formulations are associated with lower rates of adverse events	1b	
compared to immediate release ones, although similar discontinuation rates are reported in clinical		
trials.		
Dose escalation of antimuscarinic drugs may be appropriate in selected patients to improve treatment	1b	
effect although higher rates of adverse events can be expected.		
Transdermal oxybutynin (patch) is associated with lower rates of dry mouth than oral antimuscarinic	1b	
drugs, but has a high rate of withdrawal due to skin reaction.		

4.2.3 Antimuscarinic drugs vs. conservative treatment

The choice of drug vs. conservative treatment of UUI is an important question.

4.2.3.1 Question

In adults with UUI, does one type of antimuscarinic drug result in a greater likelihood of cure or improvement in UUI and/or greater improvement in QoL, and/or lesser likelihood of adverse effects compared to conservative treatment?

4.2.3.2 Evidence

More than 100 RCTs and high-quality reviews are available [158, 176, 189, 190, 202, 203]. Most of these studies were independent. A US HTA [176] found that trials were of a low- or moderate-quality. The main focus of the review was to compare the different drugs used to treat UUI. In one study, multicomponent behavioural modification produced significantly greater reductions in incontinence episodes compared to oxybutynin and higher patient satisfaction for behavioural vs. drug treatment. In men with storage LUTS no difference in efficacy was found between oxybutynin and behavioural therapy [204].

The combination of BT and solifenacin in women with OAB conferred no additional benefit in terms of continence [205]. A recent Cochrane review on the benefit of adding PFMT to other active treatments of UI in women showed insufficient evidence of any benefit in adding PFMT to drug treatment [206].

One RCT [207] reported a similar improvement in subjective parameters with either transcutaneous electrical nerve stimulation (T-PTNS) or oxybutynin. One study compared tolterodine ER to transvaginal/anal electrical stimulation without differences in UI outcomes [208].

Summary of evidence	LE
There is no consistent evidence to show superiority of drug therapy over conservative therapy for	1b
treatment of urgency urinary incontinence.	
Behavioural treatment has higher patient satisfaction than drug treatment.	1b
There is insufficient evidence as to the benefit of adding pelvic floor muscle training to drug treatment	1b
for urgency urinary incontinence.	

4.2.3.3 Recommendations for antimuscarinic drugs

Recommendations	GR
Offer antimuscarinic drugs for adults with urgency urinary incontinence who failed conservative	А
treatment.	
Consider extended release formulations in patients who do not tolerate immediate release	А
antimuscarinics.	
If antimuscarinic treatment proves ineffective, consider dose escalation or offering an alternative	В
treatment.	
Consider using transdermal oxybutynin if oral antimuscarinic agents cannot be tolerated due to dry	В
mouth.	
Offer and encourage early review (of efficacy and side effects) of patients on antimuscarinic	С
medication for urgency urinary incontinence.	

4.2.4 Antimuscarinic agents: adherence and persistence

Most studies on antimuscarinic medication are short term (twelve weeks). Adherence in clinical trials is considered to be much higher than in clinical practice [209].

4.2.4.1 Question

Do patients with UUI adhere to antimuscarinic drug treatment and persist with prescribed treatment in clinical practice?

4.2.4.2 Evidence

This topic has been reviewed for the development of these Guidelines [210]. Two open-label extensions of RCTs of fesoterodine 8 mg showed adherence rates at two years of 49-84% [211, 212]. The main drugs studied were oxybutynin and tolterodine IR and ER. Non-persistence rates were high for tolterodine at twelve months, and particularly high (68-95%) for oxybutynin.

Five articles reported 'median days to discontinuation' as between < 30 days and 50 days [213-217]. In a military health system where free medication was provided, the median time to discontinuation extended to 273 days [214].

Data on adherence/persistence from open-label extension populations are questionable as these patients are self-selected to be compliant. A Longitudinal Disease Analyser database study has indicated an increasing discontinuation rate from 74.8% at one year to 87% at three years [218].

Several of the RCT trials tried to identify the factors associated with low/lower, adherence or persistence of antimuscarinics. These were identified as:

- low level of efficacy (41.3%);
- adverse events (22.4%);
- cost (18.7%), higher adherence rates were observed when drugs were provided at no cost to the patient [214].

Other reasons for poor adherence included:

- IR vs. ER formulations;
- age (lower persistence among younger adults);
- unrealistic expectations of treatment;
- gender distribution (better adherence/persistence in female patients);
- ethnic group (African-Americans and other ethnic minorities are more likely to discontinue or switch treatment).

In addition, the data source influenced the adherence figures.
Summary of evidence	LE
Adherence to antimuscarinic treatment is low and decreases over time because of lack of efficacy,	2
adverse events and/or cost.	
Most patients will stop antimuscarinic agents within the first three months.	2

4.2.5 Antimuscarinic and beta3 agonist agents, the elderly and cognition

Trials have been conducted in elderly people with UI. Considerations in this patient group include the multifactorial aetiology of UI in the elderly, comorbidities such as cognitive impairment, the effect of co-medications and the risk of adverse events.

The effects of antimuscarinic agents on cognition have been studied in more detail.

4.2.5.1 Question

What is the comparative efficacy, and risk of adverse effects, particularly the cognitive impact, of treatment with antimuscarinic medication in elderly men and women with UUI?

4.2.5.2 Evidence

Two systematic reviews focusing on elderly patients are available [219, 220]. A community-based cohort study found a high incidence of cognitive dysfunction [221]. Other systematic reviews have included sections on the efficacy and safety of antimuscarinics in elderly patients [157, 189]. A systematic review in 2012 found inconclusive evidence as to the impact of antimuscarinics on cognition [222].

Two recent longitudinal cohort studies in patients using drugs with antimuscarinic effect showed a deterioration in cognitive function, alteration in CNS metabolism and an association with brain atrophy [223, 224]. In general, the long-term impact of antimuscarinic agents specifically approved for OAB treatment on specific patient cohorts is poorly understood [225-228].

4.2.5.2.1 Oxybutynin

There is evidence that oxybutynin IR may cause/worsen cognitive dysfunction in adults [225, 227, 229-233]. Recent evidence has emerged from a prospective cohort study showing cumulative cognitive deterioration associated with prolonged use of antimuscarinic medication including oxybutynin [223].

More rapid functional deterioration might result from the combined use of cholinesterase inhibitors with antimuscarinic agents in elderly patients with cognitive dysfunction [234].

4.2.5.2.2 Solifenacin

One pooled analysis [235] has shown that solifenacin does not increase cognitive impairment in the elderly. No age-related differences in the pharmacokinetics of solifenacin in different age groups was found, although more frequent adverse events in subjects over 80 years of age were observed. No cognitive effect on healthy elderly volunteers was shown [233]. In a subanalysis of a large trial, solifenacin 5-10 mg improved symptoms and QoL in people \geq 75 years who had not responded to tolterodine [236]. In patients with mild cognitive impairment, \geq 65 years, solifenacin showed no difference in efficacy between age groups and a lower incidence of most side effects compared to oxybutynin IR [232, 237].

4.2.5.2.3 Tolterodine

No change in efficacy or side effects related to age have been reported, although a higher discontinuation rate was found for both tolterodine and placebo in elderly patients [225]. Two RCTs in the elderly found a similar efficacy and side effect profile to younger patients [238-241]. Post-hoc analysis has shown little effect on cognition. One non-randomised comparison showed lower rates of depression in elderly participants treated with tolterodine ER compared to oxybutynin IR [242].

4.2.5.2.4 Darifenacin

Two RCTs in the elderly population (one in patients with UUI and the other in volunteers) concluded that darifenacin was effective with no risk of cognitive change, measured as memory scanning tests, compared to placebo [243, 244]. Another study on darifenacin and oxybutynin ER in elderly subjects concluded that the two agents had a similar efficacy, but that cognitive function was more often affected in the oxybutynin ER arm [227].

4.2.5.2.5 Trospium chloride

Trospium does not appear to cross the blood brain barrier in significant amounts in healthy individuals due to its molecular characteristics (quaternary amine structure and hydrophilic properties). Two (EEG) studies in healthy volunteers showed no effect from trospium whilst tolterodine caused occasional changes and oxybutynin caused consistent changes [245, 246]. No evidence as to the comparative efficacy and side effect profiles of trospium in different age groups in available. However, there is some evidence that trospium does not impair cognitive function [228, 247] and that it is effective compared to placebo in the elderly [248].

4.2.5.2.6 Fesoterodine

Pooled analyses of the RCTs of fesoterodine confirmed the efficacy of the 8 mg but not the 4 mg dose in over-75-year olds [211]. Adherence was lower in the over-75 year-old group but the effect on mental status was not reported [201, 211, 249]. A more recent RCT showed efficacy of fesoterodine in the vulnerable elderly with no differences in cognitive function at twelve weeks [250].

4.2.5.2.7 Duloxetine in the elderly

RCTs comparing duloxetine and placebo included women up to 85 years, but no age stratification of the results is available [190, 251, 252].

4.2.5.2.8 Mirabegron

Analysis of pooled data from three RCTs showed efficacy and safety of mirabegron in elderly patients [253].

4.2.5.2.9 Applicability of evidence to general elderly population

It is not clear how much the data from pooled analyses and subgroup analyses from large RCTs can be extrapolated to a general ageing population. Community-based studies of the prevalence of antimuscarinic side effects may be the most helpful [221]. When starting anticholinergics in elderly patients, mental function should be assessed objectively and monitored [254]. No consensus exists as to the best mental function test to detect changes in cognition [234, 255].

4.2.5.2.10 Anticholinergic load

A number of medications have anticholinergic effects and their cumulative effects on cognition should be considered [256].

4.2.5.2.11 Question

In older people suffering from UI, what is the effect of anticholinergic burden (defined by anticholinergic cognitive burden scale) on cognitive function?

4.2.5.2.12 Evidence

No studies were identified specifically in older people with UI, but evidence was available from observational cohort studies relating to the risk in a general population of older people. Lists of drugs with anticholinergic properties are available from two sources [256, 257].

Two systematic reviews of largely retrospective cohort studies showed a consistent association between long-term anticholinergic use and cognitive dysfunction [258, 259].

Longitudinal studies in older people over two to four years have found increased rate of decline in cognitive function for patients on anticholinergics or drugs with anticholinergic effects [223, 224, 260, 261].

Summary of evidence	LE
Antimuscarinic drugs are effective in elderly patients.	1b
Mirabegron has been shown to be efficacious and safe in elderly patients.	1b
In older people, the cognitive impact of drugs which have anticholinergic effects is cumulative and	2
increases with length of exposure.	
Oxybutynin may worsen cognitive function in elderly patients.	2
Solifenacin, darifenacin, fesoterodine and trospium have been shown not to cause cognitive	1b
dysfunction in elderly people in short-term studies.	

4.2.5.2.13 Additional recommendations for antimuscarinic drugs in the elderly

Recommendations	GR
In older people being treated for urinary incontinence, every effort should be made to employ	С
Tionpharmacological treatments first.	D*
who are at risk of, or have, cognitive dysfunction.	D
When prescribing antimuscarinic for urgency urinary incontinence, consider the total antimuscarinic	С
load in older people on multiple drugs.	
Consider the use of mirabegron in elderly patients if additional antimuscarinic load is to be avoided.	С
	4

"Recommendation based on expert opinion.

4.2.5.3 Research priorities

- All drug trials should report cure rates for urinary incontinence based on a bladder diary.
- What is the relative incidence of cognitive side effects of antimuscarinic drugs?

4.2.6 Mirabegron

Mirabegron is the first clinically available beta3 agonist, available from 2013. Beta3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation.

Mirabegron has undergone evaluation in industry-sponsored phase 2 and phase 3 trials [262-265]. Three systematic reviews assessing the clinical effectiveness of mirabegron [262, 263, 266] reported that mirabegron at doses of 25, 50 and 100 mg, results in significantly greater reduction in incontinence episodes, urgency episodes and micturition frequency/24 hours than placebo, with no difference in the rate of common adverse events [262]. The placebo dry rates in most of these trials are between 35-40%, and 43 and 50% for mirabegron. In all trials the statistically significant difference is consistent only for improvement but not for cure of UI. Similar improvement in frequency of incontinence episodes and micturitions/24 hours was found in people who had previously tried and those who had not previously tried antimuscarinic agents. One systematic review showed that mirabegron is similarly efficacious as most antimuscarinics in reducing UUI episodes [267].

The most common treatment adverse events in the mirabegron groups were hypertension (7.3%), nasopharyngitis (3.4%) and UTI (3%), with the overall rate similar to placebo [262, 265, 268].

In a twelve-month, active-controlled RCT of mirabegron 50/100 mg vs. tolterodine ER 4 mg, the improvement in efficacy seen at twelve weeks was sustained at twelve-month evaluation in all groups. The reported dry rates at twelve months were 43%, 45% and 45% for mirabegron 50 mg, 100 mg and tolterodine 4 mg respectively [268]. Post hoc analyses of RCTs showed that clinical improvement observed in parameters of OAB severity translates to an improvement in HRQoL and efficacy is maintained in patients with more severe degree of UI [269, 270].

No risk of QTc prolongation on electrocardiogram [271] and raised intraocular pressure [272] were observed up to 100 mg dose; however, patients with uncontrolled hypertension or cardiac arrhythmia were excluded from these trials. There is no significant difference in rate of side effects at different doses of mirabegron [268]. Data from a large Canadian Private Drug Plan database suggest a higher adherence rate for mirabegron compared to antimuscarinics [273]. Patients on certain concurrent medications (i.e. metroprolol) should be counselled that, due to common metabolism pathways, their medication dosage may need to be adjusted. In the case of patients taking metoprolol, blood pressure should be monitored after starting mirabegron and, if necessary, metoprolol dosing changed.

Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron (50 or 100 mg) did not adversely affect voiding urodynamic parameters compared to placebo [274].

Equivalent adherence was observed for tolterodine and mirabegron at twelve months (5.5% and 3.6%), although the incidence of dry mouth was significantly higher in the tolterodine group [268]. In mirabegron treated patients, improvement in objective outcome measures correlates directly with clinically relevant PROMs (OAB-q and PPBC) [269, 275].

An RCT in patients who had inadequate response to solifenacin monotherapy 5 mg, demonstrated that

combination treatment with mirabegron 50 mg had a higher chance of achieving clinically meaningful improvement in UI as compared to dose escalation of solifenacin [276].

Summary of evidence	LE
Mirabegron is better than placebo and as efficacious as antimuscarinics for improvement of urgency	1a
urinary incontinence symptoms.	
Adverse event rates with mirabegron are similar to placebo.	1a
Patients inadequately treated with solifenacin 5 mg may benefit more from the addition of mirabegron	1b
than dose escalation of solifenacin.	

Recommendation	GR
In patients with UUI and an inadequate response to conservative treatments offer mirabegron, unless	А
they have uncontrolled hypertension.	

4.2.7 Drugs for stress urinary incontinence

Duloxetine inhibits the presynaptic re-uptake of neurotransmitters, serotonin (5-HT) and norepinephrine (NE). In the sacral spinal cord, an increased concentration of 5-HT and NE in the synaptic cleft increases stimulation of 5-HT and NE receptors on the pudendal motor neurones, which in turn increases the resting tone and contraction strength of the urethral striated sphincter.

4.2.7.1 Questions

- In adults with SUI, does duloxetine cure or improve UI and/or improve QoL compared to no treatment?
- In adults with SUI, does duloxetine result in a greater cure or improvement of UI, or a greater improvement in QoL, or a lesser likelihood of adverse effects, compared to any other intervention?

4.2.7.2 Evidence

Duloxetine was evaluated as a treatment for female SUI or MUI in three systematic reviews [190, 251, 252].

Improvement in UI compared to placebo was observed with no clear differences between SUI and MUI. One study reported cure for UI in about 10% of patients. An improvement in I-QoL was not found in the study using I-QoL as a primary endpoint. In a further study comparing duloxetine, 80 mg daily, with PFMT alone, PFMT + duloxetine, and placebo [277], duloxetine reduced leakage compared to PFMT or no treatment. Global improvement and QoL were better for combined therapy than no treatment. There was no significant difference between PFMT and no treatment.

Two open-label studies with a follow-up of one year or more evaluated the long-term effect of duloxetine in controlling SUI; however, both had high discontinuation rates [278, 279].

All studies had a high patient withdrawal rate, which was caused by a lack of efficacy and high incidence of adverse events, including nausea and vomiting (40% or more of patients), dry mouth, constipation, dizziness, insomnia, somnolence and fatigue, amongst other causes [278, 279].

A systematic review showed significant efficacy for duloxetine compared to placebo in women with UI but with increased risk of adverse events [252].

Summary of evidence	LE
Duloxetine, 40 mg twice daily improves stress urinary incontinence in women.	1a
Duloxetine causes significant gastrointestinal and central nervous system side effects leading to a high	1a
rate of treatment discontinuation, although these symptoms are limited to the first weeks of treatment.	

Recommendations	GR
Duloxetine can be used with caution to treat women with symptoms of stress urinary incontinence.	А
Duloxetine should be initiated using dose titration because of high adverse event rates.	А

4.2.8 Oestrogen

Oestrogenic drugs including conjugated equine oestrogens, oestradiol, tibolone and raloxifene, are used as hormone replacement therapy (HRT) for women with natural or therapeutic menopause.

Oestrogen treatment for UI has been tested using oral, transdermal and vaginal routes of administration. Available evidence suggests that vaginal oestrogen treatment with oestradiol and oestriol is not associated with the increased risk of thromboembolism, endometrial hypertrophy, and breast cancer seen with systemic administration [280-282]. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women.

4.2.8.1 Questions

- In women with UI, does vaginal (local) oestrogen cure or improve UI compared to no treatment or other active treatment?
- In women with UI, does oral (systemic) oestrogen cure or improve UI compared to no treatment?

4.2.8.2 Evidence

Vaginal oestrogens

A Cochrane systematic review looked at the use of oestrogen therapy in postmenopausal women [280] given local oestrogen therapy. There is also a more recent narrative review of oestrogen therapy in urogenital diseases [283]. The Cochrane review (search date cut off June 2012) found that vaginal oestrogen treatment improved symptoms of UI in the short term [280]. The review found small, low quality trials comparing vaginal oestrogen treatment with phenylpropanolamine, PFMT, electrical stimulation and its use as an adjunct to surgery for SUI. Local oestrogen was less likely to improve UI than PFMT but no differences in UI outcomes were observed for the other comparisons. A single trial of local oestrogen therapy comparing a ring device to pessaries found no difference in UI outcomes although more women preferred the ring device. No adverse effects of vaginal administration of oestradiol for vulvovaginal atrophy over two years was seen in one trial [284].

Vaginal oestrogen therapy can be given as conjugated equine oestrogen, oestriol or oestradiol in vaginal pessaries, vaginal rings or creams. The ideal treatment duration and the long-term effects are uncertain. A standardised review of local oestrogen showed improvement of UI over placebo with vaginal rings favoured subjectively over pessaries; no significant difference between vaginal and oral oestrogen treatments was found [285].

One RCT in postmenopausal women showed benefit in adding intravaginal oestriol to vaginal ES and PFMT [286].

Systemic oestrogens

Studies of HRT with non-urogenital primary outcomes have looked for change in urinary continence in secondary analyses. Large trials using conjugated equine oestrogens showed a higher rate of development or worsening of UI compared to placebo [287-290]. In a single RCT, use of raloxifene was not associated with development or worsening of UI [291]. Three small RCTs using oral oestriol or oestradiol as HRT for vulvovaginal atrophy suggested that UI symptoms were improved although the evidence was unclear [50, 292, 293].

Summary of evidence	LE
Vaginal oestrogen therapy improves urinary incontinence for post-menopausal women in the short	1a
term.	
Neoadjuvant or adjuvant use of local oestrogens are ineffective as an adjunct to surgery for urinary	2
incontinence.	
Systemic hormone replacement therapy using conjugate equine oestrogens in previously continent	1a
women increases the risk of developing urinary incontinence and worsens pre-existing urinary	
incontinence.	

Recommendations	GR
Offer post-menopausal women with urinary incontinence vaginal oestrogen therapy, particularly if	А
other symptoms of vulvovaginal atrophy are present.	
Vaginal oestrogen therapy for vulvovaginal atrophy should be prescribed long-term. In women with a	С
history of breast cancer, the treating oncologist needs to be consulted.	
For women taking oral conjugated equine oestrogen as hormone replacement therapy who develop or	А
experience worsening urinary incontinence, discuss alternative hormone replacement therapies.	
Advise women who are taking systemic oestradiol who suffer from urinary incontinence that stopping	А
the oestradiol is unlikely to improve their incontinence.	

4.2.9 **Desmopressin**

Desmopressin is a synthetic analogue of vasopressin (also known as antidiuretic hormone). It can be taken orally, nasally or by injection. Desmopressin is most commonly used to treat diabetes insipidus and, when used at night, to treat nocturnal enuresis.

4.2.9.1 Questions

- In adults with UI, does desmopressin cure or improve UI and/or improve QoL compared to no treatment?
- In adults with UI, does desmopressin result in a lesser likelihood of adverse effects, compared to any other intervention?

4.2.9.2 Evidence

4.2.9.2.1 Improvement of incontinence

Few studies have examined the use of desmopressin exclusively for the treatment of UI. No evidence was found that demonstrated any effect of desmopressin on nocturnal incontinence, though evidence does exist for it reducing nocturnal polyuria, particularly in children [294]. One RCT compared desmopressin to placebo with daytime UI as an outcome measure, with improved continence shown during the first four hours after taking desmopressin in women [295]. There is no evidence reporting desmopressin cure rates for UI and no evidence that compares desmopressin with other non-drug treatments for UI.

4.2.9.2.2 Monitoring for hyponatraemia

The use of desmopressin carries a risk of developing hyponatraemia (please refer to the EAU Guidelines on Male LUTS [27]).

Summary of evidence	LE
The risk of urinary incontinence is reduced within four hours of taking oral desmopressin, but not after	1b
four hours.	
Continuous use of desmopressin does not improve or cure urinary incontinence.	1b
Regular use of desmopressin may lead to hyponatraemia.	3

Recommendations	GR
Consider offering desmopressin to patients requiring occasional short-term relief from daytime urinary	А
incontinence and inform them that this drug is not licensed for this indication.	
Monitor plasma sodium levels in patients on desmopressin.	A*
Do not use desmopressin for long-term control of urinary incontinence.	А

*Recommendation based on expert opinion.

4.2.10 Drug treatment in mixed urinary incontinence

4.2.10.1 Question

In adults with MUI, is the outcome of a drug treatment different to that for the same treatment in patients with either pure SUI or UUI?

4.2.10.2 Evidence

Many RCTs include patients with MUI with predominant symptoms of either SUI or UUI but few report outcomes separately for those with MUI compared to pure SUI or UUI groups.

Tolterodine

In an RCT of 854 women with MUI, tolterodine ER was effective for improvement of UUI, but not SUI suggesting that the efficacy of tolterodine for UUI was not altered by the presence of SUI [296]. In another study (n = 1380) tolterodine was equally effective in reducing urgency and UUI symptoms, regardless of whether there was associated SUI [297]. Similar results were found for solifenacin [298, 299].

Duloxetine

In one RCT of duloxetine vs. placebo in 588 women, subjects were stratified into either stress-predominant, urgency-predominant or balanced MUI groups. Duloxetine was effective for improvement of incontinence and QoL in all subgroups [300].

Duloxetine was found to have equal efficacy for SUI and MUI in an RCT (n = 553) following secondary analysis of respective subpopulations [301].

Summary of evidence	LE
Limited evidence suggests that antimuscarinic drugs are effective for improvement of the urgency	2
urinary incontinence component in patients with mixed urinary incontinence.	
Duloxetine is effective for improvement of both stress urinary incontinence and urgency urinary	1b
incontinence in patients with mixed urinary incontinence.	

Recommendations	GR
Treat the most bothersome symptom first in patients with mixed urinary incontinence.	С
Offer antimuscarinic drugs or beta3 agonists to patients with urgency-predominant mixed urinary	A*
incontinence.	
Consider duloxetine for patients with mixed urinary incontinence unresponsive to other conservative	В
treatments and who are not seeking cure.	

*Recommendation based on expert opinion.

4.3 Surgical management

In line with the recommendations from the UK National Institute for Healthcare and Clinical Excellence (NICE) [50] the Panel agreed that surgeons and centres performing surgery should:

- be properly trained in each procedure;
- not be trained by someone who is not surgically qualified;
- perform sufficient numbers of a procedure to maintain expertise of him/herself and the surgical team;
- be able to offer alternative surgical treatments;
- be able to deal with the complications of surgery;
- provide suitable arrangements for follow-up, long-term if necessary.

This section considers surgical options for the following situations:

- Women with uncomplicated SUI: This means no history of previous surgery, no neurogenic LUT dysfunction, no bothersome genitourinary prolapse, and women not considering further pregnancy.
- Women with complicated SUI: Neurogenic LUT dysfunction is reviewed in the EAU Guidelines on Neuro-Urology [2].
- Associated genitourinary prolapse has been included in these Guidelines in terms of treating incontinence, but no attempt has been made to comment on treatment of prolapse itself.
- Men with SUI: mainly men with post-prostatectomy incontinence without neurological disease affecting the lower urinary tract.
- Patients with refractory DO incontinence.

Although the outcome of surgical procedures should be considered in absolute terms, it is also important to consider any associated complications, adverse events and costs. The outcome parameters used to evaluate surgery for SUI have included:

- continence rate and number of incontinence episodes;
- general and procedure-specific complications;
- generic, specific (UI) and correlated (sexual and bowel) QoL.

The Panel has tried to acknowledge emerging techniques as they considered appropriate and have made a strong recommendation (section 4.3.1.5.2) that new devices are only used as part of a structured research programme.

4.3.1 Women with uncomplicated stress urinary incontinence

4.3.1.1 Mid-urethral slings

Early clinical studies identified that slings should be made from monofilament, non-absorbable material, typically polypropylene, and constructed as a 1-2 cm wide mesh with a relatively large pore size (macroporous). Mid-urethral slings are now the most frequently used surgical intervention in Europe for women with SUI.

4.3.1.1.1 Questions

In women with SUI, what is the effectiveness in curing SUI and adverse effects at one year for:

- mid-urethral synthetic sling insertion compared to Burch colposuspension?
- one method of insertion of a mid-urethral synthetic sling compared to another method?
- one direction of insertion of a mid-urethral synthetic sling compared to another direction of insertion?

4.3.1.1.2 Evidence

For the purpose of these Guidelines, a new meta-analysis was performed.

Mid-urethral sling insertion compared to colposuspension

Thirteen RCTs (n = 1037) compared mid-urethral sling (retropubic) and colposuspension (open and laparoscopic). The meta-analysis found no difference in patient-reported cure rates at twelve months [302-312]. The overall patient-reported cure rate was 75%. There was weak evidence of higher clinician-reported cure rates at twelve months after mid-urethral sling (83%) compared to colposuspension (78%) [305-312]. Longer-term follow-up for up to five years reported no difference in effectiveness, though the numbers of participants lost to follow-up was high [76, 304]. Voiding dysfunction was more likely for colposuspension (relative risk 0.34, 95% CI 0.16-0.7) whilst bladder perforation was higher for the mid-urethral sling (15% vs. 9%, and 7% vs. 2%, respectively) [303, 305, 313-315].

Transobturator route vs. retropubic route

The EAU Panel meta-analysis identified 34 RCTs (5,786 women) comparing insertion of the mid-urethral sling by the retropubic and transobturator routes. There was no difference in cure rates at twelve months in either patient-reported or clinically reported cure rates (77% and 85%, respectively) [5]. Voiding dysfunction was less common (4%) following transobturator insertion compared to retropubic insertion (7%), as was the risk of bladder perforation (0.3%) or urethral perforation (5%). The risks of *de novo* urgency and vaginal perforation were 6% and 1.7%, respectively. Chronic perineal or groin/thigh pain at twelve months after surgery was reported by 21 trials and meta-analysis showed a higher rate in women undergoing transobturator insertion (7%) compared to retropubic insertion (3%).

Insertion using a skin-to-vagina direction vs. a vagina-to-skin direction

A Cochrane systematic review and meta-analysis found that the skin-to-vagina direction (top - down) for retropubic insertion of mid-urethral slings was less effective than the vagina-to-skin (bottom - up) direction and was associated with higher rates of voiding dysfunction, bladder perforation and vaginal erosion [316]. A further systematic review and meta-analysis found that the skin-to-vagina (outside in) direction of transobturator insertion of mid-urethral slings was equally effective compared to the vagina-to-skin route (inside out) using direct comparison. However, indirect comparative analysis gave weak evidence for a higher rate of voiding dysfunction and bladder injury [317].

4.3.1.2 Adjustability

4.3.1.2.1 Questions

- In women with SUI, does an adjustable sling cure SUI and improve QoL or does it cause adverse outcome(s)?
- How does an adjustable sling compare to other surgical treatments for SUI?

4.3.1.2.2 Evidence

There are no RCTs investigating outcome of adjustable sling insertion for women with SUI. There are limited data from cohort studies on adjustable tension slings with variable selection criteria and outcome definitions. Few studies include sufficient numbers of patients or have a long enough follow-up to provide useful evidence. The available devices have differing designs, making it difficult to draw general conclusions about adjustable slings as a class of procedure.

4.3.1.3 Single-incision slings

4.3.1.3.1 Questions

- In women with SUI, do single-incision slings cure UI or improve QoL, or cause adverse outcomes?
- How does a single-incision sling compare to other surgical treatments for SUI?

4.3.1.3.2 Evidence

Although there have been many studies published on single-incision devices, it should be noted that there are significant differences in technical design between devices and it may be misleading to make general statements about them as a class of operations. It should also be noted that some devices have been withdrawn from the market (e.g. TVT Secur[®], Minitape), and yet evidence relating to these may be included in current meta-analyses. There was evidence to suggest single-incision slings are quicker to perform and cause less post-operative thigh pain, but there was no difference in the rate of chronic pain. There was not enough evidence to conclude any difference between single-incision slings in direct comparisons.

The most recent meta-analysis [318] and a re-analysis of the Cochrane review data by the Panel (excluding TVT Secur[®] data) have demonstrated that there was no difference in efficacy between available single-incision devices and conventional mid-urethral slings. However, not all single-incision devices have been subjected to RCT evaluation and it may be unsafe to assume that they are collectively technically similar devices.

Generalisability of evidence to adult women with SUI

Analysis of the population studied in trials included in this meta-analysis suggests that the evidence is generalisable to women who have predominantly SUI, and no other clinically severe lower genitourinary tract dysfunction. The evidence is not adequate to guide choice of surgical treatment for those women with MUI, severe POP, or a history of previous surgery for SUI. The results of the EAU Panel meta-analysis [5] were consistent with those of the Cochrane systematic review [316], except that in the EAU Panel meta-analysis the objective cure rates appeared slightly higher for retropubic (88%) compared to transobturator insertion (84%). The EAU Panel finding is consistent with an additional systematic review and meta-analysis [319] and the difference may result from the Panel's decision to only consider trial data with at least twelve months of follow-up.

Sexual function after mid-urethral tape surgery

A systematic review concluded there was a lack of RCTs addressing the effects of incontinence surgery on sexual function but noting a reduction in coital incontinence [320]. One RCT [321] and another cohort study [322] have shown that overall sexual activity improves after sling surgery.

SUI surgery in the elderly

There are no RCTs comparing surgical treatment in older vs. younger women, although subgroup analyses of some RCTs have included a comparison of older with younger cohorts. Definitions of elderly vary from one study to another so no attempt was made to define the term here. Instead, the Panel attempted to identify those studies which have addressed age difference as an important variable.

A RCT of 537 women comparing retropubic to transobturator tape, showed that increasing age was an independent risk factor for failure of surgery over the age of 50 [323]. An RCT assessing risk factors for the failure of TVT vs. transobturator tension-free vaginal tape (TVT-O) in 162 women found that age is a specific risk factor (adjusted OR 1.7 per decade) for recurrence at one year [324]. In a subanalysis of a trial cohort of 655 women at 2 years' follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up (OR 3.7, 95% CI 1.7-7.97), are less likely to report objective or subjective improvement in stress and urgency UI, and are more likely to undergo retreatment for SUI (OR 3.9, 95% CI 1.3-11.48). There was no difference in time to post-operative normal voiding [325].

Another RCT comparing immediate TVT vs. no surgery (delayed TVT) in older women, confirmed efficacy of surgery in terms of QOL and satisfaction, but with higher complication rates [326].

A cohort study of 256 women undergoing inside-out transobturator tape reported similar efficacy in older vs. younger women, but found a higher risk of *de novo* urgency in older patients [327].

Summary of evidence	LE
Compared to colposuspension, the retropubic insertion of a mid-urethral synthetic sling provides	1a
equivalent patient-reported cure of stress urinary incontinence at five years.	
Mid-urethral synthetic sling inserted by either the transobturator or retropubic route provides	1a
equivalent patient-reported outcome at twelve months.	
Mid-urethral sling insertion is associated with a lower rate of a new symptom of urgency, and voiding	1a
dysfunction, compared to colposuspension.	
The retropubic route of insertion is associated with a higher intra-operative risk of bladder perforation	1a
and a higher rate of voiding dysfunction than the transobturator route.	
The transobturator route of insertion is associated with a higher risk of chronic pain and vaginal	1a
erosion and extrusion at twelve months, than that found with the retropubic route.	
The skin-to-vagina direction of both retropubic and transobturator insertion is associated with a higher	1b
risk of post-operative voiding dysfunction.	
Adjustable mid-urethral synthetic sling devices may be effective for cure or improvement of stress	3
urinary incontinence in women.	
There is no evidence that adjustable slings are superior to standard mid-urethral slings.	4
The comparative efficacy of single-incision slings against conventional mid-urethral slings is uncertain.	1b

Operation times for insertion of single-incision mid-urethral slings are shorter than for standard retropubic slings.	1b
Blood loss and immediate post-operative pain are lower for insertion of single-incision slings compared with conventional mid-urethral slings.	1b
There is no evidence that other adverse outcomes from surgery are more or less likely with single- incision slings than with conventional mid-urethral slings.	1b
Older women benefit from surgical treatment for urinary incontinence.	1
The risk of failure from surgical repair of stress urinary incontinence, or suffering adverse events, appears to increase with age.	2
There is no evidence that any surgical procedure has greater efficacy or safety in older women than another procedure.	4
In women undergoing surgery for stress urinary incontinence, coital incontinence is likely to improve.	3
Overall, sexual function is unlikely to deteriorate following stress urinary incontinence surgery.	3
There is no consistent evidence that the risk of post-operative sexual dysfunction differs between midurethral sling procedures.	3

NB: Most evidence on single-incision slings is from studies using the tension-free vaginal tape secure (TVTS)

device and although this device is no longer available, many women still have the device in place.

4.3.1.4 Open and laparoscopic surgery for stress urinary incontinence

Open colposuspension was previously considered the most appropriate surgical intervention for SUI, and was used as the comparator in RCTs of newer, less invasive, surgical techniques. These include laparoscopic techniques, which have enabled colposuspension to be performed with a minimally invasive approach.

4.3.1.4.1 Question

In women with SUI, what is the effectiveness of open and laparoscopic surgery, compared to other surgical procedures, measured in terms of cure or improvement of incontinence or QoL, or the risk of adverse events?

4.3.1.4.2 Evidence

Four systematic reviews were found, which covered the subject of open surgery for SUI, including 46 RCTs [2, 328-330], but no RCTs comparing any operation to a sham procedure were identified.

Open colposuspension

The Cochrane review [330] included 46 trials in which 4,738 women had open colposuspension. In most of these trials, open colposuspension was used as the comparator to an experimental procedure. Consequently, for this review we have only considered the absolute effect of colposuspension, but have not reviewed all of these comparisons. No additional trials have been reported since this review.

Within the first year, complete continence rates of approximately 85-90% were achieved for open colposuspension, while failure rates for UI were 17% up to five years and 21% over five years. The re-operation rate for UI was 2%. Colposuspension was associated with a higher rate of development, at five years, of enterocoele/vault/cervical prolapse (42%) and rectocele (49%) compared to tension-free vaginal tape (TVT) (23% and 32%, respectively). The rate of cystocoele was similar in colposuspension (37%) and with TVT (41%).

Four trials compared Burch colposuspension to the Marshall Marchetti Krantz procedure and one trial evaluated Burch colposuspension with paravaginal repair. All showed fewer surgical failures up to five years with colposuspension but otherwise reported similar outcomes.

Anterior colporrhaphy

Anterior colporrhaphy is now considered an obsolete operation for UI. In a Cochrane review [329], ten trials compared anterior colporrhaphy (n = 385) with colposuspension (n = 627). The failure rate for UI at follow-up of up to five years was worse for anterior colporrhaphy with a higher requirement for re-operation for incontinence.

Autologous fascial sling

The Cochrane review [329, 331] described 26 RCTs, including 2,284 women undergoing autologous sling procedure in comparison to other operations.

There were seven trials of autologous fascial sling vs. colposuspension. Except for one very high-quality study [49] showing superiority of fascial sling most of the studies were of variable quality, with a few very small studies and short follow-up. The meta-analysis showed that fascial sling and colposuspension had a similar cure rate at one year. Colposuspension had a lower risk of voiding difficulty and UTIs, but a higher risk of bladder perforation.

In twelve trials of autologous fascial sling vs. mid-urethral synthetic slings, the procedures showed similar efficacy. However, use of the synthetic sling resulted in shorter operating times and lower rates of complications, including voiding difficulty. Six trials compared autologous fascial slings with other materials of different origins, with results favouring traditional autologous fascial slings. Post-hoc analysis of an RCT comparing the autologous fascial sling to Burch colposuspension showed inferior outcomes for women who suffered pre-operative urgency [325].

Laparoscopic colposuspension

The Cochrane review [328] identified 22 RCTs, of which ten trials compared laparoscopic colposuspension to open colposuspension. No other trials have been identified. Although these procedures had a similar subjective cure rate, there was limited evidence suggesting the objective outcomes were less good for laparoscopic colposuspension. However, laparoscopic colposuspension had a lower risk of complications and shorter duration of hospital stay.

In eight RCTs comparing laparoscopic colposuspension to mid-urethral slings, the subjective cure rates were similar, while the objective cure rate favoured the mid-urethral sling at eighteen months. Complication rates were similar for the two procedures and operating times were shorter for the mid-urethral sling. Comparisons of colposuspension to mid-urethral sling are covered in section 4.3.1.1.

Summary of evidence	LE
Autologous fascial sling is more effective than colposuspension for improvement of stress urinary	1b
incontinence.	
Laparoscopic colposuspension has similar efficacy to open colposuspension for cure of stress urinary	1a
incontinence and a similar risk of voiding difficulty or de novo urgency.	
Laparoscopic colposuspension has a lower risk of other complications and shorter hospital stay than	1a
open colposuspension.	
Autologous fascial sling has a higher risk of operative complications than open colposuspension,	1b
particularly voiding dysfunction and post-operative urinary tract infection.	

4.3.1.5 Bulking agents

4.3.1.5.1 Question

In women with SUI, does injection of a urethral bulking agent cure SUI or improve QoL, or cause adverse outcomes?

4.3.1.5.2 Evidence

There have been two Cochrane systematic reviews [332, 333] and one independent systematic review [334], which reported on twelve RCTs or quasi-RCTs of injectable agents. In general, the trials were only of moderate quality and small, with many of them only being reported in abstract form. Wide confidence intervals meant a meta-analysis was not possible. Since the Cochrane review, two further RCTs have been reported [335, 336].

Each injectable product has been the subject of many case series. Short-term efficacy in reducing the symptoms of SUI has been demonstrated for all materials used. In 2006, NICE published an extensive review of these case series [50]. These case series have added very little to the evidence provided by RCTs. There has been only one placebo-controlled RCT, in which an autologous fat injection was compared with the placebo of a saline injection.

Comparison with open surgery

Two RCTs compared collagen injection to conventional surgery for SUI (autologous sling vs. silicon particles and collagen vs. assorted procedures). The studies reported greater efficacy but higher complication rates for open surgery. In comparison, collagen injections showed inferior efficacy but equivalent levels of satisfaction and fewer serious complications [50, 337].

Another trial found that a peri-urethral route of injection can carry a higher risk of urinary retention compared to a transurethral injection [338]. A recent small RCT found no difference in efficacy between mid-urethral and bladder neck injection of collagen [335].

Summary of evidence	LE
Peri-urethral injection of bulking agent may provide short-term improvement in symptoms (three	2a
months), but not cure, in women with stress urinary incontinence.	
Repeat injections to achieve therapeutic effect are often required.	2a
Bulking agents are less effective than colposuspension or autologous sling for cure of stress urinary	2a
incontinence.	
Adverse effect rates are lower compared to open surgery.	2a
There is no evidence that one type of bulking agent is better than another type.	1b
Transperineal route of injection may be associated with a higher risk of urinary retention compared to	2b
the transurethral route.	

Recommendations	GR
Offer the mid-urethral sling to women with uncomplicated stress urinary incontinence as the preferred	А
surgical intervention whenever available.	
Warn women who are being offered a retropubic insertion of mid-urethral sling about the relatively	А
higher risk of peri-operative complications compared to transobturator insertion.	
Warn women who are being offered transobturator insertion of mid-urethral sling about the higher risk	А
of pain and dyspareunia in the longer term.	
Warn women who are being offered a single-incision sling that long-term efficacy remains uncertain.	А
Do a cystourethroscopy as part of the insertion of a mid-urethral sling.	С
Offer colposuspension (open or laparoscopic) or autologous fascial sling for women with stress urinary	А
incontinence if mid-urethral sling cannot be considered.	
Warn women undergoing autologous fascial sling that there is a high risk of voiding difficulty and the	С
need to perform clean intermittent self-catheterisation; ensure they are willing and able to do so.	
Inform older women with stress urinary incontinence about the increased risks associated with	В
surgery, including the lower probability of success.	
Inform women that any vaginal surgery may have an impact on sexual function.	В
Only offer new devices, for which there is no level 1 evidence base, as part of a structured research	A*
programme.	
Only offer adjustable mid-urethral sling as a primary surgical treatment for stress urinary incontinence	A*
as part of a structured research programme.	
Do not offer bulking agents to women who are seeking a permanent cure for stress urinary	A*
incontinence.	

* Recommendation based on expert opinion.

4.3.2 Complicated stress urinary incontinence in women

This section will address surgical treatment for women who have had previous surgery for SUI, which has failed, or those women who have undergone previous radiotherapy affecting the vaginal or urethral tissues. Neurogenic LUT dysfunction is reviewed by the EAU Guidelines on Neuro-Urology [2]. Women with associated genitourinary prolapse are included in this edition (see section 4.3.3).

4.3.2.1 Colposuspension or sling following failed surgery

There may be persistent or recurrent SUI, or the development of *de novo* UUI. This means that careful evaluation including urodynamics becomes an essential part of the work-up of these patients.

4.3.2.1.1 Question

In women who have had failed surgery for SUI, what is the effectiveness of any second-line operation, compared to any other second-line operation, in terms of cure or improvement of UI, QoL or adverse events?

4.3.2.1.2 Evidence

Most of the data on surgery for SUI refer to primary operations. Even when secondary procedures have been included, it is unusual for the outcomes in this subgroup to be separately reported. When they are, the numbers of patients is usually too small to allow meaningful comparisons.

The 4th International Consultation on Incontinence includes a review of this topic [1] up to 2008, and the subject has also been reviewed by Ashok [339] and Lovatsis *et al.* [340]. A further literature review has been carried out since that time by the Panel.

Cochrane reviews of individual operative techniques have not included separate evaluation of outcomes in women undergoing second-line surgery. However, there is a current protocol to address this issue [341]. Only one RCT was found (abstract only) comparing TVT to laparoscopic colposuspension in women with recurrent SUI. This small study found similar cure rates and adverse events in the short term for both procedures [315].

Post-hoc subgroup analysis of high-quality RCTs comparing one procedure to another have shown conflicting evidence of relative effectiveness [74, 325, 342, 343]. One large non-randomised comparative series suggested that cure rates after more than two previous operations were 0% for open colposuspension and 38% for fascial sling [344].

Several cohort studies have reported outcomes for TVT specifically for primary and secondary cases. Evidence on the effectiveness of second-line retropubic tapes conflicts with some series showing equivalent outcomes for primary and secondary cases [345, 346], whilst other research has shown inferior outcomes for secondary surgery [347, 348]. Other confounding variables make meaningful conclusions difficult.

Systematic review of older trials of open surgery for SUI suggest that the longer-term outcomes of redo open colposuspension may be poor compared to autologous fascial slings [349]. Successful results have been reported from mid-urethral slings after various types of primary surgery, while good outcomes are reported for both repeat TVT and for 'tightening' of TVT, but data are limited to small case series only.

Summary of evidence	LE
There is conflicting evidence whether prior surgery for stress incontinence or prolapse results in	2
inferior outcomes from repeat operations for stress urinary incontinence.	
Most procedures will be less effective when used as a second-line procedure than when used for	2
primary surgery.	
In women who have had more than two procedures for stress urinary incontinence, the results of open	2
colposuspension are inferior to autologous fascial sling.	

4.3.2.2 External compression devices

External compression devices are still widely used in the treatment of recurrent SUI after the failure of previous surgery and if there is thought to be profound intrinsic failure of the sphincter mechanism, characterised by very low leak point pressures or low urethral closure pressures. This should be confirmed by urodynamic evaluation.

The two intracorporeal external urethral compression devices available are the adjustable compression therapy (ACT) device and the artificial urinary sphincter (AUS). Using ultrasound or fluoroscopic guidance, the ACT device is inserted by placement of two inflatable spherical balloons on either side of the bladder neck. The volume of each balloon can be adjusted through a subcutaneous port placed within the labia majora. More recently, an adjustable artificial urinary sphincter (FlowsecureTM) has been introduced. It has the added benefit of 'conditional occlusion', enabling it to respond to rapid changes in intra-abdominal pressure.

4.3.2.2.1 Questions

- In women with SUI, does insertion of an external compressive device cure SUI, improve QoL or cause adverse outcomes?
- How do external compression devices compare to other surgical treatments for SUI?

4.3.2.2.2 Evidence

The major advantage of AUS over other anti-incontinence procedures is the perceived ability to be able to void normally [111]. However, voiding dysfunction is a known side effect, with a lack of data making it difficult to assess its importance. Because of significant differences in design between devices and in selection criteria between case series, results obtained with specific devices cannot be extrapolated generally to the use of adjustable devices. A recent consensus report has standardised the terminology used for reporting complications arising from implantation of materials into the pelvic floor region [17].

Artificial urinary sphincter (AUS)

A previous review of mechanical devices concluded that there was insufficient evidence to support the use of AUS in women [350].

There are a few case series in women, including four series (n = 611), with study populations ranging from 45 to 215 patients and follow-up ranging from one month to 25 years [351-354]. Case series have been confounded by varying selection criteria, especially the proportion of women who have neurological dysfunction or who have had previous surgery. Most patients achieved an improvement in SUI, with reported subjective cures in 59-88%. Common side effects included mechanical failure requiring revision (up to 42% at ten years) and explantation (5.9-15%). In a retrospective series of 215 women followed up for a mean of six years, the risk factors for failure were older age, previous Burch colposuspension and pelvic radiotherapy [354]. Peri-operative injury to the urethra, bladder or rectum was also a high-risk factor for explantation [352].

A newly introduced artificial sphincter using an adjustable balloon capacity through a self-sealing port, and stress responsive design, has been introduced to clinical use. A series of 100 patients reported 28% explantation at four years but the device has undergone redesign and more up-to-date evidence is awaited [355]. Early reports of laparoscopically implanted AUS do not have sufficient patient populations and/or sufficient follow-up to be able to draw any conclusions [356, 357].

Adjustable compression device (ACT)

There are four case series (n = 349), with follow-up ranging from five to 84 months [358-361]. Reported outcome ranged from 47% objective cure to 100% subjective improvement. However, most patients required adjustment to achieve continence and 21% required explantation.

Summary of evidence	LE
Implantation of an artificial sphincter can improve or cure incontinence in women with stress urinary	3
incontinence caused by sphincter insufficiency.	
Implantation of the adjustable compression therapy (ACT) device may improve complicated urinary	3
incontinence.	
Complications, mechanical failure and device explantation often occur with both the artificial sphincter	3
and the adjustable compression device.	
Explantation is more frequent in older women and among those who have had previous Burch	3
colposuspension or pelvic radiotherapy.	

Recommendations	GR
Management of complicated stress urinary incontinence should only be offered in expert** centres.	A*
The choice of surgery for recurrent stress urinary incontinence should be based on careful evaluation	С
of the individual patient including multichannel urodynamics and imaging as appropriate.	
Warn women with recurrent stress urinary incontinence that the outcome of a surgical procedure,	С
when used as a second-line treatment, is generally inferior to its use as a first-line treatment, both in	
terms of reduced efficacy and increased risk of complications.	
Consider secondary synthetic sling, colposuspension or autologous sling as first options for women	С
with complicated stress urinary incontinence.	
Warn women receiving artificial urinary sphincter or ACT device that, even in expert centres, there is a	С
high risk of complications, mechanical failure or a need for explantation.	

* Recommendation based on expert opinion.

** Expert centres refers to the comments on surgeon volume in the introduction to the surgical chapter.

4.3.3 Women with both stress urinary incontinence and pelvic organ prolapse

There is a clear association between the presence of POP and SUI. Although the subject of prolapse is not part of the remit of these Guidelines, the extent to which it impacts on the management of SUI will be addressed. The aim is to assess the options available to women who require surgery for POP and who have associated UI (either symptomatic or after reduction of prolapse), and to assess the value of prophylactic anti-incontinence surgery in women with no evidence of UI.

4.3.3.1 Questions

1. In women with POP and UI, does combined surgery for POP and SUI reduce the incidence of post-operative UI compared to POP surgery alone?

- 2. In continent women with POP, does combined surgery for POP and SUI reduce the incidence of post-operative *de novo* UI compared to POP surgery alone?
- 3. In women with POP and occult SUI, (i.e. seen only on prolapse reduction stress testing/ urodynamics), does combined surgery for POP and SUI reduce the incidence of postoperative UI compared to POP surgery alone?
- 4. In women with POP and OAB, does surgery for POP improve OAB symptoms?
- 5. In adults with POP, what is the reliability, the diagnostic accuracy and predictive value of a prolapse reduction test to identify patients at risk from *de novo* SUI following prolapse repair?

4.3.3.2 Evidence

A Cochrane review in 2013 included sixteen trials concerning bladder function after surgery for pelvic organ prolapse [362]. After prolapse surgery 434 of 2125 women (20.4%) reported new subjective SUI, in sixteen trials. New voiding dysfunction was reported in 109 of 1,209 (9%) women, in twelve trials.

1. In women with POP does combined surgery for POP and SUI reduce the incidence of postoperative UI compared to POP surgery alone?

There are two well-designed RCTs relating to the prevalence of post-operative SUI in women who underwent prolapse surgery with and without an anti-incontinence procedure. Both of these trials involved women with POP who did not complain of symptoms of stress incontinence regardless of objective findings.

One trial compared abdominal sacrocolpopexy with and without Burch colposuspension [363], the other compared vaginal repair with and without a mid-urethral sling [364]. In both trials addition of an antiincontinence surgery reduced the risk of SUI at twelve months. In one trial there was a higher rate of adverse events reported in the combined surgery group [364]. This was also the finding of the Cochrane review and meta-analysis.

Two trials addressed post-operative SUI in patients who had had SUI pre-operatively. Borstad *et al.*, in a multicentre trial, randomised women with POP and SUI to have a tension-free vaginal tape (TVT) at the time of prolapse repair or three months later, if they still had SUI. (n = 53). One year after surgery there was no difference between the groups regarding continence; however, 44% of the women without initial TVT never required surgery and 29% were dry [365].

In contrast, Costantini *et al.* followed-up women with POP and SUI randomised to abdominal POP repair with or without Burch colposuspension (after a median of 97 months), finding that additional SUI surgery did not improve outcome [366]. On the contrary, a higher number of patients had *de novo* storage symptoms when a Burch colposuspension was performed.

In summary, it is difficult to generalise the results of trials using very different procedures to treat both POP and UI. It seems that with a combined procedure the rate of SUI post-operatively is lower. Studies using midurethral slings have generally shown more significant differences in UI outcomes with combined procedures than when other types of anti-incontinence procedure have been used. Individual patient characteristics may play the most important role in shaping treatment decisions. It must be taken into account that, although more women may be dry after combined surgery, the risks of repeat surgery, should it become necessary, may outweigh the potential benefits.

2. Continent women with POP

The 2013 Cochrane review included 6 trials showing that post-operative incontinence rates at < twelve months were 19% in the combined surgery group vs. 32% in POP surgery alone. In this group of 438 women, undergoing continence surgery at the time of prolapse prevented 62 (14%) women from developing *de novo* SUI post-prolapse surgery. A long-term update of a previously published RCT comparing POP surgery with or without Burch colposuspension in continent women suggested higher UI rates in women undergoing colposuspension [364].

3. Women with POP and occult SUI

The 2013 Cochrane review included five trials addressing this point. Overall, there was a significantly higher rate of post-operative patient-reported SUI with prolapse surgery alone than compared with combined surgery.

4. Women with POP and OAB

There are three case series evaluating patients with concomitant OAB and pelvic organ prolapse which

assess incontinence/OAB symptom scores post-surgical repair. Costantini *et al.* assessed the effect of posterior repair on OAB/DO and reported a 70-75% improvement rate in both parameters along with a 93% anatomic success rate [367]. Kummeling *et al.* assessed the effect of a modified laparoscopic sacrocolpopexy on urodynamic parameters and reported an improvement with no evidence to support a concomitant prophylactic colposuspension [368]. Lee *et al.* assessed the value of pre-op urodynamic study and bladder outlet obstruction index (BOOI) in predicting the degree of OAB symptoms post anterior prolapse repair. They reported a significant correlation between low pre-op BOOI and improvement in OAB symptom scores post-op [369].

Prolapse reduction stress test (PRST)

5.

Data concerning PRST were made available from the CARE trial, where significant differences were noted in the detection of urodynamic stress incontinence with prolapse reduction among the various methods studied, ranging from 6% (pessary) to 30% (speculum). Manual, swab and forceps showed detection rates of 16%, 20% and 21%, respectively [370]. In the study by Duecy, about one third of women were diagnosed with occult SUI using a pessary while two thirds were diagnosed with manual reduction of the prolapse [371]. In a further study occult SUI was only detected by a pessary test in 19% of patients, not by urodynamics, history or clinical examination [372].

Summary of evidence	LE
Women with prolapse + urinary incontinence	
Surgery for pelvic organ prolapse (POP) + stress urinary incontinence shows a higher rate of cure of	1a
urinary incontinence in the short term than POP surgery alone.	
There is conflicting evidence on the relative long-term benefit of surgery for POP + stress urinary	1b
incontinence vs. POP surgery alone.	
Combined surgery for POP + stress urinary incontinence carries a higher risk of adverse events.	1b
Continent women with pelvic organ prolapse	
Are at risk of developing urinary incontinence post-operatively.	1a
The addition of a prophylactic anti-incontinence procedure reduces the risk of post-operative urinary	1b
incontinence.	
The addition of a prophylactic anti-incontinence procedure increases the risk of adverse events.	1b
Women with pelvic organ prolapse and overactive bladder	
There is some low-level inconsistent evidence to suggest that surgical repair of POP can improve	3
symptoms of overactive bladder.	
Surgery for POP + occult stress urinary incontinence shows a higher rate of cure of occult stress	1a
urinary incontinence in the short term than POP surgery alone.	
Combined surgery for POP + stress urinary incontinence carries a higher risk of adverse events than	1b
POP surgery alone.	

Recommendations for women requiring surgery for bothersome pelvic organ prolapse who	GR
have symptomatic or unmasked stress urinary incontinence	
Offer simultaneous surgery for pelvic organ prolapse and stress urinary incontinence.	А
Warn women of the increased risk of adverse events with combined surgery compared to prolapse	А
surgery alone.	
Recommendations for women requiring surgery for bothersome pelvic organ prolapse without	
symptomatic or unmasked stress urinary incontinence.	
Warn women that there is a risk of developing de novo stress urinary incontinence after prolapse	А
surgery.	
Inform women that the benefit of prophylactic stress urinary incontinence surgery is uncertain.	С
Warn women that the benefit of surgery for stress urinary incontinence may be outweighed by the	А
increased risk of adverse events with combined surgery compared to prolapse surgery alone.	

4.3.4 Urethral diverticulum

A female urethral diverticulum is a sac-like protrusion made up by the entire urethral wall or only by the urethral mucosa situated between the periurethral tissues and the anterior vaginal wall. Urethral diverticulum give rise to a variety of symptoms that include pain, urgency, frequency, recurrent UTIs, vaginal discharge, dyspareunia, voiding difficulties or urinary incontinence.

4.3.4.1 Question

In a woman with the clinical suspicion of having a urethral diverticulum, what is the best test to confirm the diagnosis?

4.3.4.2 Evidence

No robust diagnostic accuracy studies address this question. However, a case series of 27 patients concluded that endoluminal (vaginal or rectal) MRI has better diagnostic accuracy than voiding cystourethrography (VCUG) [373]. In a case series of 60 subjects Pathi, *et al.* reported that the sensitivity, specificity, positive predictive value and negative predictive value of MRI is 100%, 83%, 92% and 100%, respectively [374]. Dwarkasing *et al.* also reports 100% specificity and sensitivity of MRI in a case series of 60 patients [375]. However, in a case series of 41 patients, a study reported 25% discrepancy between MRI and surgical findings [376].

4.3.4.3 Question

In a woman who has a bothersome urethral diverticulum, what is the relative effectiveness of available surgical treatments?

4.3.4.4 Surgical treatment

No RCTs were found. Surgical removal is the most commonly reported treatment in contemporary case series. However, recurrence may occur; Han *et al.* found a recurrence rate of 33% in U-shaped and of 60% in circumferential diverticulum within one year [377], Ingber *et al.* found a 10.7% recurrence rate in 122 women undergoing diverticulectomy, with a higher risk of recurrence in those with proximal or multiple diverticula or after previous pelvic surgery [378]. SUI may occur in up to 20% of women after diverticulectomy, requiring additional correction [379-382]. *De novo* SUI seems to be more common in proximal and in large size (> 30 mm) diverticula.

Diverticula may undergo neoplastic alterations (6%) including invasive adenocarcinomas [383].

Summary of evidence	LE
Magnetic resonance imaging has good sensitivity and specificity for the diagnosis of urethral	3
diverticula; however, there is a risk of misdiagnosis and missing potential intraluminal neoplastic	
change.	
Surgical removal of symptomatic urethral diverticula provides good long-term results; however,	3
women should be counselled of the risk of recurrence and <i>de novo</i> stress urinary incontinence.	

Recommendation	GR
Symptomatic urethral diverticula should be completely surgically removed.	A*

* Recommendation based on expert opinion.

4.3.5 Men with stress urinary incontinence

In men who fail conservative treatment (see chapter 4.1.3.3.5) other treatments can be considered.

4.3.5.1 Drug therapy

Three RCTs suggest an earlier recovery of continence in men receiving duloxetine either alone [384], or in addition to PFMT, for post prostate surgery SUI [385, 386].

Summary of evidence	LE
Duloxetine, either alone or combined with conservative treatment, can hasten recovery of continence	1b
but does not improve continence rate following prostate surgery.	

4.3.5.2 Bulking agents in men

Injection of bulking agents has been used to try and improve the coaptation of a damaged sphincter zone. Initial reports showed limited efficacy in treating incontinence following radical prostatectomy incontinence [387, 388].

4.3.5.2.1 Question

In men with post-prostatectomy incontinence or SUI, does injection of a urethral bulking agent cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.2.2 Evidence

Most studies are case series with small sample sizes. Small cohort studies showed a lack of benefit using a number of different materials [389, 390]. However, polyacrylamide hydrogel resulted in limited improvement in QoL without curing the UI [389]. A Cochrane review on the surgical treatment of post-prostatectomy incontinence found only one study that fulfilled the inclusion criteria [391]. A prospective, randomised study compared the AUS to silicon particles (Macroplastique[™]) in 45 patients. Eighty-two per cent of patients receiving an AUS were continent compared to 46% receiving silicone particles. In patients with severe incontinence, outcome was significantly worse after silicon bulking injection.

4.3.5.3 Fixed male sling

In addition to external compression devices and bulking agents, slings have been introduced to treat post-prostatectomy incontinence. Fixed slings are positioned under the urethra and fixed by a retropubic or transobturator approach. The tension is adjusted during the surgery and cannot be re-adjusted post-operatively.

For the restoration of continence by these male slings, two concepts are now being proposed:

- continence restoration by urethral compression (InVance[®], Istop TOMS, Argus[®]);
- continence restoration by repositioning the bulb of urethra (AdVance[™]) [392].

In principle, the AUS can be used for all degrees of post-prostatectomy incontinence, while male slings are advocated for mild-to-moderate UI. However, the definitions of mild and moderate UI are not clear. The definition of cure, used in most studies, was no pad use or one security pad per 24 hours. Some authors used a stricter criterion of less than 2 g urine loss in a 24-hour pad test [393].

4.3.5.3.1 Question

In men with post-prostatectomy SUI, does insertion of a fixed suburethral sling cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.3.2 Evidence

Concerning the surgical treatment of post-prostatectomy incontinence, three recent literature reviews are available [394-396]. There are a large number of uncontrolled case series concerning men implanted with several types of slings [397, 398].

For the repositioning sling (AdVanceTM), the benefit after a mean follow-up of three years has been published on 136 patients [399]. Earlier data were available from other cohort studies, totalling at least 614 patients with a mean follow-up of between three months and three years. Subjective cure rates for the device vary between 8.6% and 73.7%, with a mean of 49.5%. Radiotherapy was a negative prognostic factor [397]. Post-operative voiding dysfunction occurred in 5.7-1.3%, while erosions and chronic pain were uncommon (0-0.4%) [393, 399-401]. The overall failure rate was about 20%.

The previously available 'InVance®' device has now been removed from the market in some countries.

Summary of evidence	LE
There is limited short-term evidence that fixed male slings cure or improve post-prostatectomy	3
incontinence in patients with mild-to-moderate incontinence.	
Men with severe incontinence, previous radiotherapy or urethral stricture surgery may have less	3
benefit from fixed male slings.	
There is no evidence that one type of male sling is better than another.	3

4.3.5.4 Adjustable slings in males

Adjustability in male sling surgery attempts to adjust the tension of the sling post-operatively. Three main systems have been used in men: the Remeex[®] system, the Argus[®] system and the ATOMS[®] system.

4.3.5.4.1 Question

In men with post-prostatectomy incontinence or SUI, does insertion of an adjustable suburethral sling cure or improve SUI, improve QoL, or cause adverse outcomes?

4.3.5.4.2 Evidence

There are no RCTs. Most studies consist of prospective or retrospective case series, with variable follow-up and different definitions of success. Some have been published only as conference abstracts.

For the Remeex[®] system, only two abstracts, with conflicting findings, have been published. One study followed nineteen patients for nearly seven years and reported 70% success, with no explants, infections or erosions. The second study followed fourteen patients for 25 months. Only 36% of patients were satisfied and multiple re-adjustments were needed. Mechanical failure was reported in 21% [402].

Argus[®] system

Data on the Argus[®] system has been reported for 404 men, but only four series have reported on more than 50 patients [403, 404], with the longest follow-up being 2.4 years. Success rates varied between 17% and 91.6%, with a mean of 57.6% predominantly reporting a subjective cure. The number of implants requiring re-adjustment was reported as between 22.9% and 41.5% [404]. Infection of the device occurred in 5.4-8% [403]. Erosions were reported in 5-10% [405]. Urethral perforations occurred in 2.7-16% [403]. Pain at the implant site was usually only temporary, but chronic pain has been reported [403, 405]. These complications resulted in explantation rates of 10-15% [404].

The ATOMS[®] system consists of a mesh implant with an integrated adjustable cushion, which uses a titanium port left in the subcutaneous tissue of the lower abdomen or scrotum for adjustment of cushion volume. Initial reports show objective cure rates of 60.5% and improvement rates of 23.7% but with the need for up to nine post-operative adjustments [406, 407].

Summary of evidence	LE
There is limited evidence that adjustable male slings can cure or improve stress urinary incontinence in	3
men.	
There is limited evidence that early explantation rates are high.	3
There is no evidence that adjustability of the male sling offers additional benefit over other types of	3
sling.	

4.3.5.5 Compression devices in males

External compression devices can be divided into two types: circumferential and non-circumferential compression of the urethral lumen [394]. The artificial urinary sphincter (AUS) is the standard treatment for moderate-to-severe male SUI. Most data available on the efficacy and adverse effects of AUS implantation are from older retrospective cohort studies with RCTs not performed due to the lack of a comparator. Men considering insertion of an AUS should understand that if the ability of an individual to operate the pump is uncertain, it may not be appropriate to implant an AUS. There are several recognised complications of AUS implantation, e.g. mechanical dysfunction, urethral constriction by fibrous tissue, erosion and infection. The non-circumferential compression devices consist of two balloons placed close to the vesico-urethral anastomotic site. The balloons can be filled and their volume can be adjusted post-operatively through an intra-scrotal port. Men who develop cognitive impairment or lose manual dexterity will have difficulty operating an AUS.

4.3.5.5.1 Question

In men with post-prostatectomy SUI, does insertion of an external compression device cure SUI, improve QoL, or cause adverse outcomes?

4.3.5.5.2 Evidence

Artificial urinary sphincter

Although the AUS is considered to be the standard treatment for men with SUI, there are two systematic reviews [391, 396] presenting limited evidence, of generally poor quality, except for one RCT comparing AUS with bulking agents [387]. A continence rate of about 80% can be expected, while this may be lower in men

who have undergone pelvic radiotherapy [394].

Trigo Rocha *et al.* published a prospective cohort study on 40 patients with a mean follow-up of 53 months, showing that from all urodynamic parameters only low bladder compliance had a negative impact on the outcome [408]. Another retrospective study showed that no urodynamic factors adversely altered the outcome of AUS implantation [409].

The transcorporeal technique of placement can be used for repeat surgery but evidence of effectiveness is lacking [410]. The dual-cuff placement was introduced to treat patients who remained incontinent with a single 4 cm cuff in place. However, it has not improved control of UI, while the availability of a 3.5 cm cuff may have eliminated the need for a dual cuff [411, 412]. Patients who experienced complete continence after AUS implantation had a higher erosion risk [413]. One small series reported results of AUS implantation after failure of previous AdVance[™] sling, showing no difference in efficacy between secondary and primary implantation [414].

Non-circumferential compression device (ProAct®)

There have been trials to treat post-prostatectomy SUI by insertion of a device consisting of balloons with adjustable volume external to the proximal bulbar urethra. A prospective cohort study (n = 128) described the functional outcome as 'good' in 68%, while 18% of the devices had to be explanted [415]. A subgroup of radiotherapy patients only had 46% success and a higher percentage of urethral erosions.

A quasi-randomised trial comparing a non-circumferential compression device (ProAct[®]) with bone-anchored male slings found that both types of device resulted in similar improvement of SUI (68% vs. 65%, respectively) [416]. Other prospective series have shown that adverse events were frequent, leading to an explantation rate of 11-58% [396, 417-420]. A questionnaire study showed that 50% of patients were still bothered significantly by persistent incontinence [421]. Other designs of artificial sphincter remain the subject of ongoing evaluation though they may have been introduced onto the market.

Summary of evidence	LE
There is evidence that primary artificial urinary sphincter (AUS) implantation is effective for cure of	2b
stress urinary incontinence in men.	
Long-term failure rate for AUS is high although device replacement can be performed.	3
There are conflicting data on whether previous pelvic radiotherapy affects the outcome of AUS	3
implantation.	
The usefulness of tandem-cuff placement is uncertain.	3
There is insufficient evidence to state whether one surgical approach for cuff placement is superior to	3
another.	
Very limited short-term evidence suggests that the non-circumferential compression device (ProACT®)	3
is effective for treatment of post-prostatectomy stress urinary incontinence.	
The non-circumferential compression device (ProACT®) is associated with a high failure and	3
complication rate leading to frequent explantation.	
The rate of explantation of the AUS because of infection or erosion remains high (up to 24% in some	3
series).	
Mechanical failure is common with the AUS.	3
Revision and re-implantation of AUS is possible after previous explantation or for mechanical failure.	3

Recommendations	GR
Consider offering duloxetine to hasten recovery of continence after prostate surgery but inform the	В
patient about the possible adverse events.	
Only offer bulking agents to men with mild post-prostatectomy incontinence who desire temporary	С
relief of incontinence symptoms.	
Do not offer bulking agents to men with severe post-prostatectomy incontinence.	С
Offer fixed slings to men with mild-to-moderate* post-prostatectomy incontinence.	В
Warn men that severe incontinence, prior pelvic radiotherapy or urethral stricture surgery, may worsen	С
the outcome of fixed male sling surgery.	
Offer AUS to men with moderate-to-severe post-prostatectomy incontinence.	В
Implantation of AUS or artificial compression device (ACT) for men should only be offered in expert	С
centres.	

Warn men receiving AUS or ACT that, even in expert centres, there is a high risk of complications,	С
mechanical failure or a need for explantation.	
Do not offer non-circumferential compression device (ProACT®) to men who have had pelvic	С
radiotherapy.	

* The terms mild and moderate post-prostatectomy incontinence remain undefined.

4.3.6 Surgical interventions for refractory detrusor-overactivity

4.3.6.1 Bladder wall injection of botulinum toxin A

Onabotulinum toxin A (onabotA; BOTOX[®]) 100 U dissolved in 10 mL of saline and injected in 20 points of the bladder wall above the trigone (0.5 mL per injection site) is licenced in Europe to treat OAB with persistent or refractory UUI in adults of both gender, despite the small number of males included in the registration trials [422, 423]. Surgeons must realise that other doses of onabotA and other formulations of botulinum toxin A, abobotulinum toxin A, are not licensed for use in UUI. Doses for onabotA are not transposable to the other brands of botulinum toxin A. The continued efficacy of repeat injections is the rule but discontinuation rate may be high. The most important adverse events related to onabotA 100 U injection detected in the regulatory trials were UTI and an increase in PVR that may require clean intermittent catheterisation [424].

4.3.6.1.1 Question

In adults with UUI, is bladder wall injection of onabotA better than no treatment for cure or improvement?

4.3.6.1.2 Evidence

Following a dose ranging study in which the 100 U of onabotA was established as the ideal dose, two phase III trials randomised (1:1) 1,105 OAB incontinent patients whose symptoms were not adequately managed with anticholinergics to receive bladder wall injections of onabotA (100 U) or saline. At baseline the population had on average more than five episodes of UUI, around twelve micturitions per day and small PVR. At week twelve, in patients treated with onabotA UUI episodes/day were halved and number of micturitions/day reduced by more than two. A total of 22.9% of the patients in the onabotA arm were fully dry, against 6.5% in the saline arm [425].

Quality of life was substantially improved in the onabotA arm, as shown by the more than 60% of positive responses in the TBS questionnaire at week twelve, which was double the positive responses in the saline arm. Cohort studies have shown the effectiveness of bladder wall injections of onabotA in the elderly and frail elderly [426], though the success rate might be lower and the PVR (> 150 mL) higher in this group.

The median time to request retreatment in the pooled analysis of the two RCTs was 24 weeks [424, 425].

A recent RCT compared onabotA injection 100 U to solifenacin (with dose escalation or switch to trospium possible in the solifenacin group) and showed similar rates of improvement in UUI over the course of six months [427]. However, patients receiving onabotA were not only more likely to have cure of UUI (27% vs. 13%, p = 0.003), but also had higher rates of urinary retention during the initial two months (5% vs. 0%) and of UTIs (33% vs. 13%). Patients taking antimuscarinics were more likely to have dry mouth.

Identification of DO in urodynamics does not influence the outcome of onabotulinum toxin A injections in patients with UUI [58].

Summary of evidence	LE
A single treatment session of onabotulinum toxin A (100 U) injected in the bladder wall is more	1a
effective than placebo at curing and improving urgency urinary incontinence and QoL.	
There is no evidence that repeated injections of onabotulinum toxin A have reduced efficacy.	3
There is a high risk of increased post-void residual when injecting elderly frail patients.	3
The risk of bacteriuria after onabotulinum toxin A (100 U) injection is high but the clinical significance	1b
of this remains uncertain.	
Onabotulinum toxin A (100 U) is superior to solifenacin for cure of urgency urinary incontinence, but	1b
rates of improvement were equivalent.	

Recommendations	GR
Offer bladder wall injections of onabotulinum toxin A (100 U) to patients with urgency urinary	А
incontinence refractory to conservative therapy (such as pelvic floor muscle training and/or	
transdermal drug treatment).	
Warn patients of the limited duration of response, risk of urinary tract infection and the possible	А
prolonged need to self-catheterise (ensure that they are willing and able to do so).	

4.3.6.2 Sacral nerve stimulation (neuromodulation)

In the first stage of a two-stage implantation, an electrode is placed percutaneously under fluoroscopic control in the sacral foramen alongside a sacral nerve, usually S3. In earlier techniques, a temporary wire electrode was used. More recently, a permanent tined electrode has been used for a longer test phase. Patients, in whom selected symptoms of UUI are reduced by more than 50% during the test phase, are candidates for the full implant, including the pulse generator and reported results only apply to this sub population.

4.3.6.2.1 Question

In adults suffering from refractory UUI, what is the clinical effectiveness of sacral nerve neuromodulation compared to alternative treatments?

4.3.6.2.2 Evidence

All randomised studies suffer from the limitation that assessors and patients were not blind to the treatment allocation since all recruited subjects had to respond to a test phase before randomisation. A Cochrane review of the literature until March 2008 [428] identified three RCTs that investigated sacral nerve stimulation in patients with refractory UUI.

One study compared implantation to controls who stayed on medical treatment and received delayed implantation at six months. Fifty percent of the immediately implanted group had > 90% improvement in UUI at six months compared to 1.6% of the control group [429]. The other RCT [430] achieved similar results, although these patients had already been included in the first report [429]. However, Weil *et al.* [430] showed that the effect on generic QoL measured by the SF-36, was unclear as it differed between the groups in only one of the eight dimensions.

The results of seventeen case series of patients with UUI, who were treated early in the experience with sacral nerve stimulation, were reviewed [431]. After a follow-up duration of between one and three years, approximately 50% of patients with UUI demonstrated > 90% reduction in UI, 25% demonstrated 50-90% improvement, and another 25% demonstrated < 50% improvement. Two case series describing the outcome of sacral nerve neuromodulation, with a mean or median follow-up of at least four years [432, 433] reported continued success (> 50% improvement on original symptoms) in patients available for follow-up. Cure rates for UUI were 15% [433].

Adverse events occurred in 50% of implanted cases, with surgical revision necessary in 33-41% [432, 433]. In a subanalysis of the RCT, the outcomes of UUI patients, with or without pre-implant DO, were compared. Similar success rates were found in patients with and without urodynamic DO [434].

Summary of evidence	LE
Sacral nerve neuromodulation is more effective than continuation of failed conservative treatment for	1b
cure of urgency urinary incontinence, but no sham controls have been used.	
In those patients who have been implanted, at long-term, 50% improvement of urgency urinary	3
incontinence is maintained in at least 50% of patients and 15% may remain cured.	
The use of tined, permanent electrodes in a staged approach results in more patients receiving the	4
final implant than occurs with temporary test stimulation.	

Recommendation	GR
Offer sacral nerve modulation to patients who have urgency urinary incontinence refractory to	А
antimuscarinic therapy.	

4.3.6.2.3 Research priority

An RCT comparing a strategy of botulinum toxin injection, repeated as required, against a strategy of test and permanent sacral nerve neuromodulation, with accompanying health economic analysis, is ongoing.

4.3.6.3 Cystoplasty/urinary diversion

4.3.6.3.1 Augmentation cystoplasty

In augmentation cystoplasty (also known as clam cystoplasty), a detubularised segment of bowel is inserted into the bivalved bladder wall. The distal ileum is the bowel segment most often used but any bowel segment can be used if it has the appropriate mesenteric length. One study did not find any difference between bivalving the bladder in the sagittal or in the coronal plane [435, 436].

There are no RCTs comparing bladder augmentation to other treatments for patients with UUI. Most often, bladder augmentation is used to correct neurogenic DO or small-capacity, low-compliant, bladders caused by fibrosis, tuberculosis, radiation or chronic infection.

The largest case series of bladder augmentation in a mixed population of idiopathic and neurogenic UUI included 51 women [437]. At an average follow-up of 74.5 months, only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UUI. It seems that the results for patients with idiopathic DO (58%) appeared to be less satisfactory than for patients with neurogenic UUI (90%).

Adverse effects were common and have been summarised in a review over five to seventeen years of more than 267 cases, 61 of whom had non-neurogenic UUI [438]. In addition, many patients may require clean intermittent self-catheterisation to obtain adequate bladder emptying (Table 3).

Short-term complications	Affected patients (%)
Bowel obstruction	2
Infection	1.5
Thromboembolism	1
Bleeding	0.75
Fistula	0.4
Long-term complications	Affected patients (%)
Clean intermittent self-catheterisation	38
Urinary tract infection	70% asymptomatic;
	20% symptomatic
Urinary tract stones	13
Metabolic disturbance	16
Deterioration in renal function	2
Bladder perforation	0.75
Change in bowel symptoms	25

Table 3: Complications of bladder augmentation

4.3.6.3.2 Detrusor myectomy (bladder auto-augmentation)

Detrusor myectomy aims to increase bladder capacity and reduce storage pressures by incising or excising a portion of the detrusor muscle, to create a bladder mucosal 'bulge' or pseudo-diverticulum. It was initially described as an alternative to bladder augmentation in children [439]. Two case series [440, 441] in adult patients with idiopathic and neurogenic bladder dysfunction, demonstrated poor long-term results caused by fibrosis of the pseudo-diverticulum. This technique is rarely, if ever, used nowadays.

4.3.6.3.3 Urinary diversion

Urinary diversion remains a reconstructive option for patients who decline repeated surgery for UI. However, there are no studies that have specifically examined this technique in the treatment of non-neurogenic UI [435].

Summary of evidence	LE
There is limited evidence on the effectiveness of augmentation cystoplasty and urinary diversion in	3
treatment of idiopathic detrusor overactivity.	
Augmentation cystoplasty and urinary diversion are associated with high risks of short-term and long-	3
term severe complications.	

The need to perform clean intermittent self-catheterisation following augmentation cystoplasty is very	3
common.	
There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty with	3
urinary diversion.	
Detrusor myectomy is ineffective in adults with urinary incontinence.	3

Recommendations	GR
Only offer augmentation cystoplasty to patients with detrusor overactivity incontinence who have	С
failed conservative therapy, in whom the possibility of botulinum toxin and sacral nerve stimulation has	
been discussed.	
Warn patients undergoing augmentation cystoplasty of the high risk of having to perform clean	С
intermittent self-catheterisation; ensure they are willing and able to do so.	
Do not offer detrusor myectomy as a treatment for urinary incontinence.	С
Only offer urinary diversion to patients who have failed less invasive therapies for the treatment of	С
urinary incontinence and who will accept a stoma.	
Warn patients undergoing augmentation cystoplasty or urinary diversion of the high risk of short-term	С
and long-term complications, and the possible small risk of malignancy.	
Lifelong follow-up is mandatory in patients who have undergone augmentation cystoplasty or urinary	С
diversion.	

4.3.7 Surgery in patients with mixed urinary incontinence

4.3.7.1 Question

In adults with MUI, is the outcome of surgery different to that obtained with the same treatment in patients with either pure SUI or pure UUI?

4.3.7.2 Evidence

Many RCTs include both patients with pure SUI or pure UUI and patients with MUI. However, very few RCTs report separate outcomes for MUI and pure UI groups.

Transvaginal obturator tape

In an RCT including 96 women with MUI, objective improvement was better for patients treated with transvaginal obturator tape + the Ingelman Sundberg operation vs. patients treated with obturator tape alone [442].

Post-hoc analysis of the SISTER trial showed that in women undergoing either autologous fascial sling or Burch colposuspension, the outcomes were poorer for women with a concomitant complaint of pre-operative urgency [325]. A similar post-hoc review of another RCT comparing transobturator and retropubic mid-urethral slings showed that the greater the severity of pre-operative urgency the more likely that treatment would fail [74]. However, an earlier study had found that surgery provided similar outcomes, whether or not urgency was present prior to surgery (this study included only a few patients with urodynamic DO).

Case series tend to show poorer results in patients with MUI compared with those with pure SUI. In a case series of 192 women undergoing mid-urethral sling insertion, overall satisfaction rates were lower for women with mixed symptoms and detrusor overactivity on pre-operative urodynamics compared to those with pure SUI and normal urodynamics (75% vs. 98%, respectively) [443]. A comparison of two parallel cohorts of patients undergoing surgery for SUI, with and without DO, found inferior outcomes in women with MUI [444].

One cohort of 450 women, showed that in urgency-predominant MUI, the success rate fell to 52% compared to 80% in stress-predominant MUI [445]. In a study with 1,113 women treated with transvaginal obturator tape, SUI was cured equally in stress-predominant MUI or urgency-predominant MUI. However, women with stress-predominant MUI were found to have significantly better overall outcomes than women with urgency predominant MUI [446].

Overall, the outcome for women with pre-existing urgency incontinence remains uncertain.

Summary of evidence	LE
Women with mixed urinary incontinence are less likely to be cured of their urinary incontinence by	1b
stress urinary incontinence surgery than women with stress urinary incontinence alone.	
The response of pre-existing urgency symptoms to stress urinary incontinence surgery is	3
unpredictable and symptoms may improve or worsen.	

Recommendations	GR
Treat the most bothersome symptom first in patients with mixed urinary incontinence.	С
Warn patients with mixed urinary incontinence that surgery is less likely to be successful than surgery	А
in patients with stress urinary incontinence alone.	
Warn patients with mixed urinary incontinence that one single treatment may not cure urinary	A*
incontinence; it may be necessary to treat other components of the incontinence problem as well as	
the most bothersome symptom.	

* Upgraded following panel consensus.

4.3.7.3 Research priorities

Research trials should define accurately what is meant by 'mixed urinary incontinence'. There is a need for well-designed trials comparing treatments in populations with MUI, and in which the type of MUI has been accurately defined.

4.3.8 Surgery for urinary incontinence in the elderly

There are no RCTs comparing surgical treatment in older vs. younger women although subgroup analyses of some RCTs have included a comparison of older with younger cohorts.

An RCT of 537 women comparing retropubic to transobturator tape, showed that cure rates decreased and failure increased with each decade over the age of 50 [447]. An RCT assessing risk factors for failure of tension free vaginal tape (TVT) vs. transobturator tension-free vaginal tape (TVT-O) in 162 women found that age is a specific risk factor (adjusted OR 1.7 per decade) for recurrence at one year [324]. In a subanalysis of the SISTER trial cohort of 655 women at 2 years of follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up (OR 3.7, 95% CI 1.7-7.97), are less likely to report objective or subjective improvement in stress and urgency UI, and are more likely to undergo retreatment for SUI (OR 3.9, 95% CI 1.3-11.48). There was no difference in time to normal post-operative voiding [325].

Another RCT compared immediate TVT vs. delayed TVT in older women, confirming significant efficacy for the women operated upon, but the cohort as a whole suffered higher complication rates, particularly bladder perforation (22%) and urinary retention (13%) [326].

A cohort study of 256 women undergoing inside-out TVT-O reported similar efficacy in older vs. younger women, but there was a higher risk of *de novo* urgency in older patients [327].

Cohort studies have shown the effectiveness of onabotulinum toxin A injections in the elderly and frail elderly [426, 448], although a comparison of cohort groups suggests that there is a lower success rate in the frail elderly and also a higher rate of increased PVR (> 150 mL) in this group.

Summary of evidence	LE
Older women benefit from surgical treatment for incontinence.	1
The risk of failure from surgical repair of stress urinary incontinence, or of suffering adverse events,	2
appears to increase with age.	
There is no evidence that any surgical procedure has greater efficacy or safety in older women than	4
another procedure.	

Recommendation	GR
Inform older women with urinary incontinence about the increased risks associated with surgery	В
(including onabotA injection), together with the lower probability of benefit.	

Figure 1: Management and treatment of women presenting with urinary incontinence.

*Based on expert opinion

Figure 2: Management and treatment of men presenting with urinary incontinence.

* Based on expert opinion

** Available evidence on onabutulinumtoxinA and sacral nerve stimulation refers mainly to women.

APPENDIX A: NON OBSTETRIC URINARY FISTULA

A.1 Introduction

The evidence relating to diagnosis and treatment of urinary fistulae is generally poor and this review inevitably relies largely on numerous case series and other consensus statements. In particular, the epidemiology, aetiology, diagnosis, treatment and prevention of non-obstetric fistulae have been described in detail during the recent International Consultations on Incontinence [449, 450]. Most non-obstetric fistulae are iatrogenic in origin, with causes including pelvic surgery (particularly hysterectomy for benign or malignant conditions, caesarean section and obstetric injuries). The risks during pelvic surgery increase relative to the complexity of the resection, the extent of primary disease and when there has been prior radiotherapy (especially for recurrent disease). When a fistula occurs following radiotherapy for primary treatment, this may be an indication of tumour recurrence.

A.2 Diagnosis of fistula

Clinical diagnosis

Leakage of urine is the hallmark sign of a fistula. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intra-operative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula [451].

The diagnosis of vesicovaginal fistula (VVF) usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection, cystoscopy, retrograde bladder filling with a coloured fluid or placement of a tampon into the vagina to identify staining may facilitate the diagnosis of a VVF. A double-dye test to differentiate between a ureterovaginal and VVF may be useful in some cases [452]. Testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this to the serum creatinine level will confirm urinary leakage.

Contrast-enhanced CT with late excretory phase reliably diagnoses urinary fistulae and provides information about ureteric integrity and the presence of associated urinoma. Magnetic resonance imaging, in particular with T2 weighting, also provides optimal diagnostic information regarding fistulae and may be preferred for urinary - intestinal fistulae [453].

A.3 Management of vesicovaginal fistula

A.3.1 Conservative management

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed or if urine is diverted. Combining available data gives an overall spontaneous closure rate of $13\% \pm 23\%$ [2], though this applies largely to small fistulae [450]. Hence, immediate management should be by urinary catheterisation or diversion.

A.3.2 Surgical management

Timing of surgery

Findings from uncontrolled case series suggest no difference in success rates for early or delayed closure of VVF.

A.3.2.1 Surgical approaches

Vaginal procedures

There are two main types of closure techniques applied to the repair of urinary fistulae, the classical saucerisation/partial colpocleisis [454] and the more commonly used dissection and repair in layers or 'flapsplitting' technique [455]. There are no data comparing their outcomes.

Abdominal procedures

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina. A transvesical repair has the advantage of being entirely extraperitoneal. A simple transperitoneal repair is used less often although it is favoured by some using the laparoscopic approach. A combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. There are no randomised studies comparing abdominal and vaginal approaches. Results of secondary and subsequent repairs are not as good as primary repair [456].

A single RCT compared trimming of the fistula edge with no trimming [457]. There was no difference in success rates but failed repairs in trimmed cases ended up with larger recurrences than untrimmed cases, which were smaller.

Laparoscopic and Robotic

Very small series (single figures) have been reported using these techniques, but whilst laparoscopic repair is feasible with and without robotic assistance, it is not possible to compare outcomes with alternative surgical approaches.

Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery. Most commonly, such flaps are utilised in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistulae, large fistulae, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high-level evidence that the use of such flaps improves outcomes for either complicated or uncomplicated VVF.

Post-operative management

There is no high-level evidence to support any particular practice in post-operative management but most reported series used catheter drainage for at least ten days and longer periods in radiation-associated fistulae (up to three weeks).

A.4 Management of radiation fistula

Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer [458]. Due to the wide field abnormality surrounding many radiotherapy-associated fistulae, approaches include, on the one hand, permanent urinary and/or faecal diversion [459, 460] or alternatively preliminary urinary and faecal diversion, with later undiversion in selected cases following reconstruction. This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate.

A.5 Management of ureteric fistula

General principles

Patients at higher risk of ureteric injury require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognise injury promptly when it occurs. Immediate repair of any intra-operative injury should be performed observing the principles of debridement, adequate blood supply and tension free anastomosis with internal drainage using stents [461]. Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvicalyceal system. Whilst there is no evidence to support the use of one surgical approach over another, there is consensus that repair should adhere to the standard principles of tissue repair and safe anastomosis, and be undertaken by an experienced team. Conservative management is possible with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< two weeks) or delayed (> three months) surgical repair when required [462]. Functional and anatomical imaging should be used to follow up patients after repair to guard against development of ureteric stricture and deterioration in renal function.

Ureterovaginal fistula

Ureterovaginal fistula occurring in the early post-operative phase predominantly after hysterectomy is the most frequent presentation of upper urinary tract fistulae in urological practice. An RCT in 3,141 women undergoing open or laparoscopic gynaecological surgery found that prophylactic insertion of ureteric stents made no difference to the low risk (1%) of ureteric injury [463].

Endoscopic management is sometimes possible [464] by retrograde stenting, percutaneous nephrostomy and antegrade stenting if there is pelvicalyceal dilatation, or ureteroscopic realignment [465].

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration.

A.6 Management of urethrovaginal fistula

Aetiology

Whilst they are rare, most urethrovaginal fistulae in adults have an iatrogenic aetiology. Causes include surgical treatment of stress incontinence with bulking agents or synthetic slings, surgery for urethral diverticulum and genital reconstruction in adults. Irradiation and even conservative treatment of prolapse with pessaries can lead to the formation of fistulae.

A.6.1 Diagnosis

Clinical vaginal examination, including the three swab test, is often sufficient to diagnose the presence of a urethrovaginal fistula. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistulae. In cases of difficult diagnosis, voiding cystourethrography (VCUG) or ultrasound can be useful. 3D MRI or CT scan is becoming utilised more widely to clarify anatomy [466, 467].

A.6.2 Surgical repair

Choice of surgery will depend on the size, localisation and aetiology of the fistula and the amount of tissue loss. Principles of reconstruction include identifying the fistula, creation of a plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall.

A.6.2.1 Vaginal approach

Goodwin described in his series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time, had less blood loss and a shorter hospitalisation time.

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: primary closure rates of 53-95.4% have been described. Pushkar *et al.* described a series of 71 women, treated for urethrovaginal fistula. 90.1% of fistulae were closed at the first vaginal intervention. Additionally, 7.4% were closed during a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation or urethrotomy [468].

Flaps and neourethra.

The simplest flap is a vaginal advancement flap to cover the urethral suture line. Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra [469, 470]. The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases a transpubic approach has been used [471]. The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernosus tissue can be incorporated in the pedicled flap and probably offers a better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome stress incontinence would occur post-operatively [472, 473].

Martius flap

While in obstetrical fistula repair it was not found to have any benefit, in a large retrospective study in 440 women the labial bulbocavernosus muscle/fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistulae where additional bulking with well vascularised tissue is needed [474]. The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomised studies [475]. The indications for Martius flap in the repair of all types of fistulae remain unclear.

Rectus muscle flap

Rectus abdominis muscle flaps have been described by some authors [476, 477].

A.6.2.2 Abdominal approach

A retropubic retrourethral technique has been described by Koriatim [478]. This approach allows a urethrovesical flap tube to be fashioned to form a continent neo-urethra.

Summary of evidence	LE
Spontaneous closure of surgical fistulae does occur, although it is not possible to establish the rate	3
with any certainty.	
There is no evidence that the timing of repair makes a difference to the chances of successful closure	3
of a fistula.	
There is no high-quality evidence of differing success rates for repair of vesicovaginal fistulae data by	3
vaginal, abdominal, transvesical and transperitoneal approaches.	
A period of continuous bladder drainage is crucial to successful fistula repair but there is no high-level	3
evidence to support one regime over another.	
A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although	3
there is little evidence to support their use in any specific setting.	
Post-radiation fistula	
Successful repair of irradiated fistulae requires prior urinary diversion and the use of non-irradiated	3
tissues to effect repair.	
Ureteric fistula	
Prophylactic ureteric stent insertion does not reduce risk of ureteric injury during gynaecological	2
surgery.	
Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often	4
palliates urinary leakage due to malignant fistula in the terminal phase.	
Urethrovaginal fistula	
Urethrovaginal fistula repair may be complicated by stress incontinence, urethral stricture and urethral	3
shortening necessitating long-term follow-up.	

Recommendations	GR
General	
Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and	С
repairing the ureter.	
Do not routinely use ureteric stents as prophylaxis against injury during routine gynaecological surgery.	В
Suspect ureteric injury or fistula in patients following pelvic surgery if a fluid leak or pelvicalyceal	С
dilatation occurs post-operatively or if drainage fluid contains high levels of creatinine.	
Suspect uretero-arterial fistula in patients presenting with haematuria with a history of relevant surgery.	С
Use three dimensional imaging techniques to diagnose and localise urinary fistulae.	С
Manage upper urinary tract fistulae by conservative or endoluminal technique where such expertise	В
and facilities exists.	
Surgical principles	
Surgeons involved in fistula surgery should have appropriate training, skills, and experience to select	С
an appropriate procedure for each patient.	
Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling and support	С
prior to and following fistula repair.	
If a vesicovaginal fistula is diagnosed within six weeks of surgery, consider indwelling catheterisation	С
for a period of up to twelve weeks after the causative event.	
Tailor the timing of fistula repair to the individual patient and surgeon requirements once any oedema,	В
inflammation, tissue necrosis, or infection, are resolved.	
Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal	С
approach is necessary.	
Ensure that the bladder is continuously drained following fistula repair until healing is confirmed	С
(expert opinion suggests: 10-14 days for simple and/or postsurgical fistulae; 14-21 days for complex	
and/or post-radiation fistulae).	
Where urinary and/or faecal diversions are required, avoid using irradiated tissue for repair.	С
Use interposition grafts when repair of radiation associated fistulae is undertaken.	С
In patients with intractable urinary incontinence from radiation-associated fistula, where life	С
expectancy is very short, consider performing ureteric occlusion.	
Repair persistent ureterovaginal fistula by an abdominal approach using open, laparoscopic or robotic	С
techniques according to availability and competence.	
Consider palliation by nephrostomy tube diversion and endoluminal distal ureteric occlusion for	С
patients with ureteric fistula associated with advanced pelvic cancer and poor performance status.	
Urethrovaginal fistulae should preferably be repaired by a vaginal approach.	С

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Neuro-Urology Guidelines aim to provide information for clinical practitioners on the incidence, definitions, diagnosis, therapy, and follow-up of neuro-urological disorders. These Guidelines reflect the current opinion of experts in this specific pathology and represent a state-of-the-art reference for all clinicians, as of the publication date.

The terminology used and the diagnostic procedures advised throughout these Guidelines follow the recommendations for investigations of the lower urinary tract (LUT) as published by the International Continence Society (ICS) [1-3]. Readers are advised to consult other EAU Guidelines that may address different aspects of the topics discussed in this document.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Neuro-Urology Guidelines Panel consists of an international multidisciplinary group of neurourological experts. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: <u>http://www.uroweb.org/guideline/neuro-urology/</u>.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is also available, both in print and as a mobile application. These are abridged versions which may require consultation with the full text version. A guideline summary has also been published in European Urology [4]. All are available through the EAU website: <u>http://www.uroweb.org/guideline/neurourology/</u>.

1.4 Publication history

The EAU published the first Neuro-Urology Guidelines in 2003 with updates in 2008, 2014, and 2016. This 2017 document represents a limited update of the 2016 publication. The literature was assessed for all chapters.

1.5 Background

The function of the LUT is mainly storage and voiding of urine, which is regulated by the nervous system that co-ordinates the activity of the urinary bladder and bladder outlet. The part of the nervous system that regulates LUT function is disseminated from the peripheral nerves in the pelvis to highly specialised cortical areas. Any disturbance of the nervous system involved, can result in neuro-urological symptoms. The extent and location of the disturbance will determine the type of LUT dysfunction, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function. Since symptoms and long-term complications do not correlate [5], it is important to identify patients with neuro-urological symptoms, and establish if they have a low or high risk of subsequent complications. The risk of developing upper urinary tract (UUT) damage and renal failure is much lower in patients with slowly progressive non-traumatic neurological disorders than in those with spinal cord injury or spina bifida [6]. In summary, treatment and intensity of follow-up examinations are based on the type of neuro-urological disorder and the underlying cause.

2. METHODS

2.1 Introduction

For the 2017 Neuro-Urology Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Neuro-Urology Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between January 1st 2013 and June 30th 2016. A total of 2,221 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/neuro-urology/?type=appendices-publications

Specific sections were updated by way of systematic reviews based on topics or questions prioritised by the Guideline Panel. These reviews were performed using standard Cochrane systematic review methodology; <u>http://www.cochranelibrary.com/about/about-cochrane-systematicreviews.html</u>.

Systematic review results included in the 2017 Neuro-Urology Guidelines are:

- 1. Continent catheterisable tubes/stomas in neuro-urological patients: A systematic review [7].
- 2. What is the long-term effectiveness and complication rate for bladder augmentation in patients with neurogenic bladder dysfunction [8]?

References used in this text are graded according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [9]. Additional information can be found in the general Methodology section of this print, and online at the EAU website; <u>http://www.uroweb.org/guideline/</u>. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

Publications ensuing from the systematic reviews have all been peer-reviewed. The 2015 Neuro-Urology Guidelines were subject to peer review prior to publication.

3. THE GUIDELINE

3.1 Epidemiology, aetiology and pathophysiology

3.1.1 Introduction

Neuro-urological symptoms may be caused by a variety of diseases and events affecting the nervous system controlling the LUT. The resulting neuro-urological symptoms depend predominantly on the location and the extent of the neurological lesion. There are no exact figures on the overall prevalence of neuro-urological disorders in the general population, but data are available on the prevalence of the underlying conditions and the relative risk of these for the development of neuro-urological symptoms. It is important to note that the majority of the data shows a very wide range of prevalence/incidence. This reflects the variability in the cohort (e.g. early or late stage disease) and the frequently small sample sizes, resulting in a low level of evidence in most published data (summarised in Table 1).

Suprapontine and pontine lesions and diseases			
Neurological Disease	Frequency in General Population	Type and Frequency of Neuro- Urological Symptoms	
Cerebrovascular accident (Strokes)	450 cases/100,000/yr (Europe) [10], 10% of cardiovascular mortality.	Nocturia - overactive bladder (OAB)- urgency urinary incontinence (UUI) - detrusor overactivity (DO), other patterns less frequent [11]. 57-83% of neuro-urological symptoms at 1 month post stroke, 71-80% spontaneous recovery at 6 months [12]. Persistence of urinary incontinence (UI) correlates with poor prognosis [13].	
Dementias: Alzheimer's disease (80%) Vascular (10%) Other (10%)	6.4% of adults > 65 yrs [14].	OAB - UUI - DO 25% of incontinence in Alzheimer's disease, > 25% in other dementias: Lewy body, NPH, Binswanger, Nasu-Hakola, Pick Disease [15]. Incontinence 3 times more frequent in geriatric patients with dementia than without [16].	

Table 1: Epidemiology of Neuro-Urological Disorders

Parkinsonian syndrome (PS) Idiopathic Parkinson's disease (IPD): 75-80% of PS	2nd most prevalent neurodegenerative disease after Alzheimer's disease. Rising prevalence of IPD with age [17].	LUTS frequency 30% at onset, 70% after 5 yrs. Storage phase symptoms: Nocturia (78%) OAB - UUI - DO [18].
Non-IPD: Parkinson's-plus (18%): - Multiple system atrophy (MSA); - Progressive supranuclear palsy; - Corticobasal degeneration; - Dementia with Lewy bodies. Secondary Parkinson's (2%)	MSA is the most frequent non-IPD PS.	OAB and DO at the initial phase, intrinsic sphincter deficiency and impaired contractility appear as the disease progress. Complications of neuro-urological symptoms (infections) account for a major cause of mortality in MSA [19]. Impaired detrusor contractility seems to be the urodynamic finding distinguishing MSA from IPD [20, 21].
Brain tumours	26.8/100,000/yr in adults (> 19 yrs), (17.9 benign, 8.9 malignant) [22].	Incontinence occurs mainly in frontal location (part of frontal syndrome or isolated in frontal location) [23].
Cerebral palsy	Cerebral palsy: 3.1-3.6/1,000 in children aged 8 yrs [24].	62% of women and 58% of men with cerebral palsy suffer from UI [25] 70% detrusor overactivity. Recurrent urinary tract infection (UTI) and radiologic abnormalities in > 10% of cases [24, 25].
Traumatic brain injury	235/100,000/yr [26]	44% storage dysfunction.38% voiding dysfunction,60% urodynamic abnormalities [27].
Lesions and diseases between c	audal brainstem and sacral spinal o	cord
Spinal cord injury (SCI)	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28].	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion
Spinal cord injury (SCI) Spina bifida (SB)	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30].	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31].
Spinal cord injury (SCI) Spina bifida (SB) Lesions and diseases of the peri	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30].	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31].
Spinal cord injury (SCI) Spina bifida (SB) <i>Lesions and diseases of the peri</i> Lumbar spine Degenerative disease Disk prolapse	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30]. Dheral nervous system Male (5%) and female (3%) > 35 yr have had a lumboscitic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr.	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31]. 26% difficulty to void and acontractile detrusor [32]. Detrusor underactivity (up to 83%) [29].
Spinal cord injury (SCI) Spina bifida (SB) <i>Lesions and diseases of the peri</i> Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30]. Dheral nervous system Male (5%) and female (3%) > 35 yr have had a lumboscitic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr.	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31]. 26% difficulty to void and acontractile detrusor [32]. Detrusor underactivity (up to 83%) [29].
Spinal cord injury (SCI) Spina bifida (SB) <u>Lesions and diseases of the peri</u> Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis Iatrogenic pelvic nerve lesions	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30]. oheral nervous system Male (5%) and female (3%) > 35 yr have had a lumboscitic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr. Rectal cancer. Cervical cancer (multimodal	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31]. 26% difficulty to void and acontractile detrusor [32]. Detrusor underactivity (up to 83%) [29]. After abdomino-perineal resection (APR): 50% urinary retention. After total mesorectal excision
Spinal cord injury (SCI) Spina bifida (SB) Lesions and diseases of the peri Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis latrogenic pelvic nerve lesions	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30]. Dheral nervous system Male (5%) and female (3%) > 35 yr have had a lumboscitic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr. Rectal cancer. Cervical cancer (multimodal therapy, radiotherapy and surgery). Endometriosis surgery.	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31]. 26% difficulty to void and acontractile detrusor [32]. Detrusor underactivity (up to 83%) [29]. After abdomino-perineal resection (APR): 50% urinary retention. After total mesorectal excision (TME): 10-30% voiding dysfunction [33].
Spinal cord injury (SCI) Spina bifida (SB) Lesions and diseases of the peri Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis latrogenic pelvic nerve lesions latrogenic pelvic nerve lesions Peripheral neuropathy Diabetes Other causes of peripheral neuropathy causing neuro- urological symptoms: alcohol abuse; lumbosacral zona and genital herpes; Guillain Barré	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [28]. Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [30]. Dheral nervous system Male (5%) and female (3%) > 35 yr have had a lumboscitic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr. Rectal cancer. Cervical cancer (multimodal therapy, radiotherapy and surgery). Endometriosis surgery. Worldwide, prevalence of pharmacologically treated diabetes 8.3% [34].	Neurogenic detrusor overactivity (NDO) and detrusor spincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (up to 83%) depending on the level of the lesion [29]. Bladder function is impaired in up to 96% of SB patients [31]. 26% difficulty to void and acontractile detrusor [32]. Detrusor underactivity (up to 83%) [29]. After abdomino-perineal resection (APR): 50% urinary retention. After total mesorectal excision (TME): 10-30% voiding dysfunction [33]. Urgency/frequency +/-incontinence [35]. Hyposensitive and detrusor underactivity at later phase [35].

Multiple sclerosis (MS) Prevalence: 8 [36].	 /100,000 in Europe 10% of MS patients present with voiding dysfunction at disease onset, 75% of patients will develop it after 10 yrs of MS [37]. DO: 86% [37]. DSD: 35% [37].

3.2 Classification systems

3.2.1 Introduction

Relevant definitions are found in the general ICS standardisation report [1, 2]. Section 3.2.2 lists the definitions from these references, partly adapted, and other definitions considered useful for clinical practice (Tables 2 and 3).

3.2.2 Definitions

Table 2: Definitions useful in clinical practice

Autonomic dysreflexia (AD)	Autonomic dysreflexia is a sudden and exaggerated autonomic response to various stimuli in patients with SCI or spinal dysfunction at or above level Th 6. It is defined as an increase in SBP > 20 mmHg from baseline [38]. Autonomic dysreflexia may be symptomatic (headache, blurred vision, stuffy nose, piloerection, flushing, sweating above the lesion level (vasodilatation), pale and cold skin (vasoconstriction) below the lesion level or asymptomatic (silent).
Bladder expression	Various manoeuvres aimed at increasing intravesical pressure in order to facilitate bladder emptying (abdominal straining, Valsalva's manoeuvre and Crede's manoeuvre) [3].
Bladder reflex triggering	Various manoeuvres performed by the patient or the therapist in order to elicit reflex detrusor contraction by exteroceptive stimuli (suprapubic tapping, thigh scratching and anal/rectal manipulation) [3].
Bladder sensation, absent	<i>During history taking</i> , the patient reports no sensation of bladder filling or desire to void [3]. <i>During filling cystometry</i> , the patient has no bladder sensation [3].
Bladder sensation, normal	<i>During history taking</i> , the patient is aware of bladder filling and increasing sensation up to a strong desire to void [3].
First sensation of bladder filling	The feeling, during filling cystometry, when the patient first becomes aware of the bladder filling [3]. <i>During filling cystometry</i> , can further be judged by the two following defined points and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints [3].
First desire to void	The feeling, during filling cystometry, that would lead the patient to pass urine at the next convenient moment, but voiding can be delayed if necessary [3].
Strong desire to void	Persistent desire to void, during filling cystometry, without the fear of leakage [3].
Bladder sensation, increased	During history taking, the patient feels an early and persistent desire to void [3]. During filling cystometry, an early first sensation of bladder filling (or an early desire to void) and/or an early strong desire to void, which occurs at low bladder volume and which persists. It is a subjective assessment, not possible to quantify [3].

Bladder sensation, non-specific	<i>During history taking</i> , the patient reports no specific bladder sensation but may perceive bladder filling as abdominal fullness, vegetative symptoms.
	or spasticity [3].
	During filling cystometry, may make the patient aware of bladder filling, for
	example, abdominal fullness or vegetative symptoms [3].
Bladder sensation, reduced	<i>During history taking</i> , the patient is aware of bladder filling but does not feel a definite desire to void [3].
	<i>During filling cystometry</i> , a diminished sensation throughout bladder filling
Catheterisation	[0]. Technique for bladder emptying employing a catheter to drain the bladder.
Cametensation	or a urinary reservoir [3]
Catheterisation indwelling	An indwelling catheter remains in the bladder urinary reservoir or urinary
Califetensation, indweiling	conduit for a period of time longer than one emptying [3].
Catheterisation, intermittent (IC)	Drainage or aspiration of the bladder or a urinary reservoir with
	subsequent removal of the catheter [3]. When not specified "self", it is
	performed by an attendant (e.g. doctor, nurse or relative).
Aseptic IC	Use of a sterile technique. This implies genital disinfection and the use of sterile catheters and instruments/gloves [3].
Clean IC	Use of a clean technique. This implies ordinary washing techniques and
	use of disposable or cleansed reusable catheters [3].
Intermittent self-catheterisation	Performed by the patient him/herself [3].
Daytime frequency, increased	Complaint by the patient who considers that he/she voids too often by
	day. This term is equivalent to pollakiuria used in many countries [3]. Many
	population-based studies of OAB have defined frequency as either eight
	or more voids/day, or eight or more voids/24 hours [39].
Diary, bladder	Records the times of micturitions and voided volumes, incontinence
	episodes, pad usage and other information such as fluid intake, the
	degree of urgency and the degree of incontinence [3].
Frequency volume chart (FVC)	Records the volumes voided as well as the time of each micturition, day
	and night, for at least 24 hours [3].
Micturition time chart	Records only the times of micturitions, day and night, for at least 24 hours [3].
Enuresis	Any involuntary loss of urine. If it is used to denote incontinence during sleep, it should always be qualified with the adjective "nocturnal" [3].
Hesitancy	Difficulty in initiating micturition resulting in a delay in the onset of voiding
	after the individual is ready to pass urine [3].
Intermittent stream (Intermittency)	Urine flow which stops and starts, on one or more occasions, during micturition [3].
Motor neuron lesion, lower	Lesion resulting from damage to motor neurons of the ventral horns or
(LMNL)	motor neuron of the cranial nerve nuclei, or resulting from interruption of the final common pathway connecting the neuron via its axon with the
	muscle fibres it innervates (the motor unit) [3].
Motor neuron lesion, upper	Lesion resulting from damage to cortical neurons that give rise to
(UMNL)	corticospinal and corticobulbar tracts. It may occur at all levels of the
	neuraxis from the cerebral cortex to the spinal cord. When rostral to
	the pyramidal decussation of the caudal medulla, they result in deficits
	below the lesion, on the contralateral side. When caudal to the pyramidal
	[40].
Neurogenic shock	Loss of vascular tone in part of the body deprived of supraspinal control.
	It commonly occurs during the acute period following spinal cord injury
	(SCI) and is associated with failure of the sympathetic nervous system. In
	this condition, systolic blood pressure < 90 mmHg in the supine posture
	is not the result of low intravascular volume (e.g. blood loss, dehydration,
	sepsis, cardiac disorders) [38].
Spinal shock	Inaracterised by marked reductions in spinal reflex activity below the level of injury [38].
Nocturia	The complaint that the individual has to wake at night one or more times
	to void [3]. Each void is preceded and followed by sleep.

Nocturnal polyuria	It is present when an increased proportion of the 24-hour output occurs at night (normally during the 8 hours whilst the patient is in bed). The night time urine output excludes the last void before sleep but includes the first void of the morning [3].
Neurogenic lower urinary tract	Lower urinary tract dysfunction (LUTD) secondary to confirmed pathology
dysfunction (NLUTD)	of the nervous supply.
Orthostatic hypotension	Symptomatic (dizziness, headache or neck ache, fatigue) or asymptomatic decrease in blood pressure defined as a drop of at least 20 mmHg systolic or 10 mmHg diastolic within 3 minutes of moving from the supine to an upright position [2, 39].
Overactive bladder syndrome	Urgency, with or without urge incontinence, usually with frequency and
(also urge syndrome or urgency-	nocturia [3].
frequency syndrome)	
Pain, genital and lower urinary tract	Abnormal sensations felt by the individual as pain, discomfort and pressure. Should be characterised by type, frequency, duration, precipitating and relieving factors and by location [3].
Bladder pain	<i>During history taking</i> , pain that is felt suprapubically or retropubically, and usually increases with bladder filling, it may persist after voiding [3]. <i>During filling cystometry</i> , is an abnormal finding [3].
Pelvic pain	Is less well defined than, for example, bladder, urethral or perineal pain and is less clearly related to the micturition cycle or to bowel function and is not localised to any single pelvic organ [3].
Perineal pain	In females, between the posterior fourchette (posterior lip of the introitus) and the anus. In males, between the scrotum and the anus [3].
Scrotal pain	May or may not be localised, for example to the testis, epididymis, cord structures or scrotal skin [3].
Urethral pain	Pain that is felt in the urethra and the individual indicates the urethra as the site [3].
Vaginal pain	Is felt internally, above the introitus [3].
Vulvar pain	Is felt in and around the external genitalia [3].
Pelvic organ prolapse	Descent of one or more of the anterior vaginal wall, the posterior vaginal wall, and the apex of the vagina (cervix/uterus) or vault (cuff) after hysterectomy. Absence of prolapse is defined as stage 0 support; prolapse can be staged from stage I to stage IV [3].
Slow stream	Perception of reduced urine flow, usually compared to previous performance or in comparison to others [3].
Spinal cord injury	Incomplete: if partial preservation of sensory and/or motor functions is found below the neurological level and includes the lowest sacral segment. Complete: when there is an absence of sensory and motor function in the lowest sacral segment [41].
Cauda equina	Injuries affecting the cauda equina and generally causing an acontractile or lower motor neuron picture affecting the LUT, distal bowel and sexual function [38].
Conal	Injuries affecting the conus medullaris of the spinal cord and often causing a mixed lesion to the LUT, distal bowel and sexual functions with a resultant either overactive or acontractile picture [38].
Supraconal	Injuries occurring above the conus medullaris. In general, supraconal injuries cause an overactive or upper motor neuron pattern of damage affecting the LUT, distal bowel and sexual functions [38].
Straining to void	Muscular effort used to either initiate, maintain or improve the urinary stream [3].
Terminal dribble	Prolonged final part of micturition, when the flow has slowed to a trickle/ dribble [3].
Urgency	The complaint of a sudden compelling desire to pass urine which is difficult to defer [3].
	Compleint of any involuntary lookage of using [2]

Stress urinary incontinence (SUI)	Complaint of involuntary leakage on effort or exertion, or on sneezing or coughing [3].
Urge urinary incontinence (UUI)	Complaint of involuntary leakage accompanied by or immediately preceded by urgency [3].
Mixed urinary incontinence	Complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing or coughing [3].
Continuous urinary incontinence	Complaint of continuous leakage [3].
Voided volume, maximum	The largest volume of urine voided during a single micturition which is determined either from the frequency/volume chart or bladder diary [3].

Table 3: Definitions useful when interpreting urodynamic studies.

Bladder compliance	Relationship between change in bladder volume and change in detrusor pressure. Compliance is calculated by dividing the volume change (ΔV) by the associated change in detrusor pressure ($\Delta pdet$) during the change in bladder volume (C= $\Delta V/\Delta pdet$). It is expressed in mL/cm H ₂ O [3].
Bladder filling, artificial	Filling the bladder, via a catheter, with a specified liquid at a specified rate [3].
Bladder filling, natural	The bladder is filled by the production of urine rather than by an artificial medium [3].
Bladder outlet obstruction	Generic term for obstruction during voiding, characterised by increased detrusor pressure and reduced urine flow rate. It is usually diagnosed by studying the synchronous values of flow rate and detrusor pressure [40].
Cystometric capacity	The bladder volume at the end of the filling cystometrogram, when "permission to void" is usually given. The volume voided together with any residual urine [3].
Maximum anaesthetic bladder capacity	The volume to which the bladder can be filled under deep general or spinal anaesthetic and should be qualified according to the type of anaesthesia used, the speed, the length of time, and the pressure at which the bladder is filled [3].
Maximum cystometric capacity	In patients with normal sensation, the volume at which the patient feels they can no longer delay micturition (has a strong desire to void) [3].
Detrusor function, normal	Allows bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation [40]. Normal voiding is achieved by a voluntarily initiated continuous detrusor contraction that leads to complete bladder emptying within a normal time span, and in the absence of obstruction. For a given detrusor contraction, the magnitude of the recorded pressure rise will depend on the degree of outlet resistance [3].
Detrusor overactivity	Urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [3].
Detrusor overactivity incontinence	Incontinence due to an involuntary detrusor contraction [3].
Idiopathic detrusor overactivity	When there is no defined cause [3].
Phasic detrusor overactivity	Is defined by a characteristic wave form and may or may not lead to UI [3].
Neurogenic detrusor overactivity	When there is a relevant neurological condition present [3].
Terminal detrusor overactivity	A single, involuntary detrusor contraction, occurring at cystometric capacity, which cannot be suppressed and results in incontinence usually resulting in bladder emptying (voiding) [3].
Detrusor sphincter dyssynergia (DSD)	A detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle. Occasionally, flow may be prevented altogether [3]. This term is specific to patients with a neurological diagnosis.

Detrusor underactivity	Contraction of reduced strength and/or duration, resulting in
,	prolonged bladder emptying and/or a failure to achieve complete
	bladder emptying within a normal time span [3].
Acontractile detrusor	Detrusor that cannot be demonstrated to contract during
	urodynamic studies [3].
Dysfunctional voiding	Intermittent and/or fluctuating flow rate due to involuntary
	intermittent contractions of the peri-urethral striated muscle during
	voiding in neurologically normal individuals [3].
Filling cystometry	Method by which the pressure/volume relationship of the bladder is
	measured during bladder filling [3].
Filling rate, physiological	Filling rate less than the predicted maximum -
	body weight (kg) /4 in mL/min [3, 42].
Filling rate, non-physiological	Filling rate greater than the predicted maximum filling rate [3, 42].
Leak point pressure, abdominal (ALPP)	The intravesical pressure at which urine leakage occurs due
	to increased abdominal pressure in the absence of a detrusor
	contraction [3].
Leak point pressure, detrusor (DLPP)	The lowest detrusor pressure at which urine leakage occurs in the
	absence of either a detrusor contraction or increased abdominal
	pressure [3].
Non-relaxing urethral sphincter	Characterised by a non-relaxing, obstructing urethra resulting in
obstruction	reduced urine flow. Usually occurs in individuals with a neurological
	lesion [3].
Post void residual (PVR)	The volume of urine left in the bladder at the end of micturition [3].
Pressure flow study	Method by which the relationship between pressure in the bladder
	and urine flow rate is measured during bladder emptying [3].
Provocative manoeuvres	Techniques used during urodynamics in an effort to provoke detrusor
	overactivity, for example, rapid filling, use of cooled or acid medium,
	postural changes and hand washing [3].
Urethral closure mechanism,	Allows leakage of urine in the absence of a detrusor contraction [3].
incompetent	
Urethral relaxation incontinence	Leakage due to urethral relaxation in the absence of raised
	abdominal pressure or detrusor overactivity [3].
Urethral closure mechanism, normal	Maintains a positive urethral closure pressure during bladder filling
	even in the presence of increased abdominal pressure, although it
	may be overcome by detrusor overactivity.
	The fluid pressure needed to just open a closed urethra [3].
	The maximum pressure of the measured profile [3].
Urethral pressure profile	A graph indicating the intraluminal pressure along the length of the
	urethra [5].
Orethral closure pressure profile	Is given by the subtraction of intravesical pressure from urethrai
	pressure [5].
	intravesical pressure [2]
(MOCF)	The length of the urethra along which the urethral proceure exceede
	intravesical pressure in women [3]
Lirethral pressure "transmission" ratio	The increment in urethral pressure on stress as a percentage of the
	simultaneously recorded increment in intravesical pressure [3]
Lirodynamic stress incontinence	The involuntary leakage of urine during increased abdominal
	pressure, in the absence of a detrusor contraction [3]
Urodynamic study ambulatory	Functional test of the lower urinary tract utilising natural filling and
	reproducing the subject's every day activities [3]
Urodynamic study, conventional	Normally takes place in the urodynamic laboratory and usually
	involve artificial bladder filling [3].
L	011

3.3 Diagnostic evaluation

3.3.1 Introduction

The normal physiological function of the LUT depends on an intricate interplay between the sensory and motor nervous systems. When diagnosing neuro-urological symptoms, the aim is to describe the type of dysfunction

involved. A thorough medical history, physical examination and bladder diary are mandatory before any additional diagnostic investigations can be planned. Results of the initial evaluation are used to decide the patient's long-term treatment and follow-up.

3.3.2 Classification systems

The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. A very simple classification system for use in daily clinical practice to decide on the appropriate therapeutic approach is provided in Figure 1 [6].

The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. Panel (A) denotes the region above the pons, panel (B) the region between the pons and the sacral cord and panel (C) the sacral cord and infrasacral region. Figures on the right show the expected dysfunctional states of the detrusor-sphincter system. Figure adapted from Panicker et al. [6] with permission from Elsevier. PVR = post-void residual.

3.3.3 Timing of diagnosis and treatment

Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders [43]. This helps to prevent irreversible changes within the LUT, even in the presence of normal reflexes [44, 45]. Furthermore, urological symptoms can be the presenting feature of neurological pathology [46, 47]. Early intervention can prevent irreversible deterioration of the LUT and UUT [48].

3.3.4 Patient history

History taking should include past and present symptoms and disorders (Table 4). It is the cornerstone of evaluation, as the answers will aid in diagnostic investigations and treatment options.

• In non-traumatic neuro-urological patients with an insidious onset, a detailed history may find that the condition started in childhood or adolescence [49].
- Urinary history consists of symptoms associated with both urine storage and emptying.
- Bowel history is important because patients with neuro-urological symptoms may also have related neurogenic bowel dysfunction [50].
- Sexual function may be impaired because of the neuro-urological condition [51].
- Special attention should be paid to possible warning signs and symptoms (e.g. pain, infection, haematuria and fever) requiring further investigation.
- Patients with SCI usually find it difficult to report UTI-related symptoms accurately [52, 53].
- The presence of urinary, bowel and sexual symptoms without neurological symptoms could be suggestive of an underlying neurological disease or condition.
- Ambulatory status after acute SCI does not predict presence or absence of unfavourable urodynamic parameters [54].

Table 4: History taking in patients with suspected neuro-urological disorder

Past history
Childhood through to adolescence and into adulthood
Hereditary or familial risk factors
Specific female: Menarche (age); this may suggest a metabolic disorder
Obstetric history
History of diabetes
Diseases, e.g. multiple sclerosis, parkinsonism, encephalitis, syphilis
Accidents and operations, especially those involving the spine and central nervous system
Present history
Present medication
Lifestyle (smoking, alcohol and drugs); may influence urinary, sexual and bowel function
Quality of life
Specific urinary history
Onset of urological history
Relief after voiding; to detect the extent of a neurological lesion in the absence of obstructive uropathy
Bladder sensation
Initiation of micturition (normal, precipitate, reflex, strain, Credé)
Interruption of micturition (normal, paradoxical, passive)
Enuresis
Mode and type of voiding (catheterisation)
Frequency, voided volume, incontinence, urgency episodes
Sexual history
Genital or sexual dysfunction symptoms
Sensation in genital area
Specific male: erection, (lack of) orgasm, ejaculation
Specific female: dyspareunia, (lack of) orgasm
Bowel history
Frequency and faecal incontinence
Desire to defecate
Defecation pattern
Rectal sensation
Initiation of defecation (digitation)
Neurological history
Acquired or congenital neurological condition
Mental status and comprehension
Neurological symptoms (somatic and sensory), with onset, evolution and any treatment
Spasticity or autonomic dysreflexia (especially in lesions at or above level Th 6)
Mobility and hand function

3.3.4.1 Bladder diaries

Bladder diaries provide data on the number of voids, voided volume, pad weight and incontinence and urgency episodes. Although a 24 hour bladder diary (recording should be done for three consecutive days) is reliable in women with UI [55, 56], no research has been done on bladder diaries in neuro-urological patients.

Nevertheless, bladder diaries are considered a valuable diagnostic tool.

3.3.5 **Patient quality of life questionnaires**

An assessment of the patient's present and expected future quality of life (QoL) is important to evaluate the effect of any therapy. Quality of life is an essential aspect of the overall management of neuro-urological patients, for example when evaluating treatment related changes on a patient's QoL [57]. The type of bladder management has been shown to affect health-related QoL (HRQoL) in patients with SCI [58] and MS [59]. Other research has also highlighted the importance of urological treatment and its impact on the urodynamic functionality of the neuro-urological patient in determining patient QoL [60].

In recent years a proliferation in the number of questionnaires to evaluate symptoms and QoL has been seen. Condition-specific questionnaires can be used to assess symptom severity and the impact of symptoms on QoL. A patient's overall QoL can be assessed using generic questionnaires. It is important that the questionnaire of choice has been validated in the neuro-urological population, and that it is available in the language that it is to be used in.

3.3.5.1 Questions

- Which validated patient questionnaires are available for neuro-urological patients?
- Which questionnaires are the most appropriate for use in neuro-urological patients?

3.3.5.2 Evidence

Three condition-specific questionnaires for urinary or bowel dysfunction and QoL have been developed specifically for adult neuro-urological patients [61]. In MS and SCI patients the Qualiveen [62, 63] is validated and can be used for urinary symptoms. A short form of the Qualiveen is available [62, 63] and it has been translated into various languages [64-67]. The Neurogenic Bladder Symptom Score (NBSS) has been validated in neurological patients to measure urinary symptoms and their consequences [68]. The QoL scoring tool related to Bowel Management (QoL-BM) [69] can be used to assess bowel dysfunction in MS and SCI patients.

In addition, sixteen validated questionnaires that evaluate QoL and asses urinary symptoms as a subscale or question in neuro-urological patients have been identified [70] (Table 5). The condition-specific Incontinence-Quality of Life (I-QoL) questionnaire which was initially developed for the non-neurological population has now also been validated for neuro-urological patients [71].

A patient's overall QoL can be assessed by generic HRQoL questionnaires, the most commonly used being the Incontinence Quality of Life Instrument (I-QOL), King's Health Questionnaire (KHQ), or the Short Form 36-item and 12-item Health Survey Questionnaires (SF-36, SF-12) [61]. In addition, the quality-adjusted life year (QALY), quantifies outcomes, by weighing years of life spent in a specified health state, adjusted by a factor representing the value placed by society or patients on their specific health state [72].

No evidence was found for which validated questionnaires are the most appropriate for use, since no quality criteria for validated questionnaires have been assessed [73].

Table 5: Patient questionnaires

Questionnaire	Underlying neurological disorder	Bladder	Bowel	Sexual function
FAMS [74]	MS	Х		X
FILMS [75]	MS	X	Х

Fransceschini [85]	SCI	Х	Х	Х

3.3.6 Physical examination

In addition to a detailed patient history, attention should be paid to possible physical and intellectual disabilities with respect to the planned investigations. Neuro-urological status should be described as completely as possible (Figure 2). Patients with a high spinal cord lesion or supraspinal neurological lesions may suffer from a significant drop in blood pressure when moved into a sitting or standing position. All sensations and reflexes in the urogenital area must be tested. Furthermore, detailed testing of the anal sphincter and pelvic floor functions must be performed (Figure 2). It is essential to have this clinical information to reliably interpret later diagnostic investigations.

3.3.6.1 Autonomic dysreflexia

Autonomic dysreflexia is a sudden and exaggerated autonomic response to various stimuli in patients with SCI or spinal dysfunction. It generally manifests at or above level Th 6. The stimulus can be distended bladder or bowel. For example, iatrogenic stimuli during cystoscopy or urodynamics can trigger AD [87]. It can also be secondary to sexual stimulation or a noxious stimulus, e.g. infected toe nail or pressure sore. Autonomic dysreflexia is defined by an increase in systolic blood pressure > 20 mmHg from baseline [38] and can have life-threatening consequences if not properly managed [88].

Figure 2: Lumbosacral dermatomes, cutaneous nerves, and reflexes

The physical examination includes testing sensations and reflexes mediated through the lower spinal cord. Abnormal findings would suggest a lesion affecting the lumbosacral segments; mapping out distinct areas of sensory impairment helps to further localise the site of the lesion. Distribution of dermatomes (areas of skin mainly supplied by a single spinal nerve) and cutaneous nerves over the perianal region and back of the upper thigh (A), the perineum [89] (B), male external genitalia [90] (C) and root values of lower spinal cord reflexes (D). Figure adapted from Panicker et al. [6] with parts A-C adapted from Standring [91], both with permission from Elsevier.

Table 6: Neurological items to be specified

Sensation S2-S5 (both sides)
Presence (increased/normal/reduced/absent)
Type (light touch/pin prick)
Affected dermatomes
Reflexes (increased/normal/reduced/absent)
Bulbocavernous reflex
Perianal/anal reflex
Knee and ankle reflexes
Plantar responses (Babinski)
Anal sphincter tone
Presence (increased/normal/reduced/absent)
Voluntary contractions of anal sphincter and pelvic muscles (increased/normal/reduced/absent)
Prostate palpation
Descensus (prolapse) of pelvic organs

3.3.6.2 Recommendations for history taking and physical examination

History taking	LE	GR*	
Take an extensive general history, concentrating on past and present symptoms including	4	A	
Pay special attention to the possible existence of alarm signs (e.g. pain, infection, haematuria,	4	A	
fever) that warrant further specific diagnosis.			
Take a specific history for each of the four mentioned functions.	4	A	
Assess quality of life when evaluating and treating the neuro-urological patient.	2a	В	
Use available validated tools including the Qualiveen and I-QoL for urinary symptoms and the QoL-BM for bowel dysfunction in multiple sclerosis and spinal cord injury patients. In addition, generic (SF-36 or KHQ) guestionnaires can be used.	1a	A	
Physical examination			
Acknowledge individual patient disabilities when planning further investigations.	4	A	
Describe the neurological status as completely as possible, sensations and reflexes in the urogenital area must all be tested.	4	A	
Test the anal sphincter and pelvic floor functions.	4	A	
Perform urinalysis, blood chemistry, bladder diary, residual and free flowmetry, incontinence quantification and urinary tract imaging.	4	A	

* All grade A recommendations are based on panel consensus.

I-QoL = Incontinence Quality of Life Instrument; OoL-BM = Quality of Life Bowel Management scoring tool; KHQ = King's Health Questionnaire; SF-36 = Short Form 36-item Health Survey Questionnaires.

3.3.7 Urodynamics

3.3.7.1 Introduction

Urodynamic investigation is the only method that can objectively assess the function and dysfunction of the LUT. In neuro-urological patients, invasive urodynamic investigation is even more challenging than in general patients. Any technical source of artefacts must be critically considered. It is essential to maintain the quality of the urodynamic recording and its interpretation [1]. Same session repeat urodynamic investigations are crucial in clinical decision making, since repeat measurements may yield completely different results [92].

In patients at risk for AD, it is advisable to measure blood pressure during the urodynamic study [93]. The rectal ampulla should be empty of stool before the start of the investigation. All urodynamic findings must be reported in detail and performed, according to the ICS technical recommendations and standards [1, 94].

3.3.7.2 Urodynamic tests

Free uroflowmetry and assessment of residual urine: Provides a first impression of the voiding function and is compulsory prior to planning any invasive urodynamics in patients able to void. For reliable information, it should be repeated at least two to three times [1]. Possible pathological findings include a low flow rate, low voided volume, intermittent flow, hesitancy and residual urine. Care must be taken when assessing the results in patients unable to void in a normal position, as both flow pattern and rate may be modified by inappropriate positions.

Filling cystometry: This test is the only method for quantifying the patient's filling function. The status of LUT function must be documented during the filling phase. However, this technique has limited use as a solitary procedure. It is much more effective combined with bladder pressure measurement during micturition and is even more effective in video-urodynamics.

The bladder should be empty at the start of filling. A physiological filling rate should be used with body-warm saline. Possible pathological findings include DO, low bladder compliance, abnormal bladder sensations, incontinence, and an incompetent or relaxing urethra.

Detrusor leak point pressure (DLPP) [95]: Appears to have no use as a diagnostic tool. Some positive findings have been reported [96, 97], but sensitivity is too low to estimate the risk to the UUT or for secondary bladder damage [98, 99].

Pressure flow study: Reflects the co-ordination between detrusor and urethra or pelvic floor during the voiding phase. It is even more powerful if combined with filling cystometry and video-urodynamics. Lower urinary tract function must be recorded during the voiding phase. Possible pathological findings include detrusor underactivity, bladder outlet obstruction (BOO), DSD, a high urethral resistance, and residual urine.

Most types of obstruction caused by neuro-urological disorders are due to DSD [100, 101], nonrelaxing urethra, or non-relaxing bladder neck [102, 103]. Pressure-flow analysis mainly assesses the amount of mechanical obstruction caused by the urethra's inherent mechanical and anatomical properties and has limited value in patients with neuro-urological disorders.

Electromyography (EMG): Reflects the activity of the external urethral sphincter, the peri-urethral striated musculature, the anal sphincter and the striated pelvic floor muscles. Correct interpretation may be difficult due to artefacts introduced by other equipment. In the urodynamic setting, an EMG is useful as a gross indication of the patient's ability to control the pelvic floor. Possible pathological findings include inadequate recruitment upon specific stimuli (e.g. bladder filling, involuntary detrusor contractions, onset of voiding, coughing, Valsalva manoeuvre) suggesting a diagnosis of DSD [104].

Urethral pressure measurement: Has a very limited role in neuro-urological disorders. There is no consensus on parameters indicating pathological findings [105].

Video-urodynamics: Is the combination of filling cystometry and pressure flow studys with imaging. It is the optimum procedure for urodynamic investigation in neuro-urological disorders. Possible pathological findings include all those described in the cystometry and the pressure flow study sections, and any morphological pathology of the LUT and reflux to the UUT [106].

Ambulatory urodynamics: This is the functional investigation of the urinary tract, which predominantly uses the natural filling of the urinary tract to reproduce the patient's normal activity. Although this type of study might be considered when conventional urodynamics does not reproduce the patient's symptoms, its role in the neuro-urological patient still needs to be determined [107, 108].

Triggered tests during urodynamics: Lower urinary tract function can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the 'ice water test') will discriminate between upper and lower motor neuron lesions [109, 110]. Patients with UMNL develop a detrusor contraction if the detrusor is intact, while patients with LMNL do not. However, the test does not seem to be fully discriminative in other types of patients [111].

Previously, a positive bethanechol test [112] (detrusor contraction > 25 cm H_2O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given equivocal results. A variation of this method was reported using intravesical electromotive administration of the bethanechol [113], but there was no published follow-up. Currently, there is no indication for this test.

3.3.7.3 Specialist uro-neurophysiological tests

The following tests are advised as part of the neurological work-up [114]:

- electromyography (in a neurophysiological setting) of pelvic floor muscles, urethral sphincter and/or anal sphincter;
- nerve conduction studies of pudendal nerve;
- reflex latency measurements of bulbocavernosus and anal reflex arcs;
- evoked responses from clitoris or glans penis;
- sensory testing on bladder and urethra.

Other elective tests, for specific conditions, may become obvious during the work-up and urodynamic investigations.

3.3.7.4 Recommendations for urodynamics and uro-neurophysiology

Recommendations	LE	GR
Record a bladder diary.	3	А
Non-invasive testing is mandatory before invasive urodynamics is planned.	4	A*
Perform a urodynamic investigation to detect and specify lower urinary tract (dys-)function, use	1b	А
same session repeat measurement as it is crucial in clinical decision making.		
Use video-urodynamics for invasive urodynamics in neuro-urological patients. If this is not	4	A*
available, then perform a filling cystometry continuing into a pressure flow study.		
Use a physiological filling rate and body-warm saline.	4	A*
Specific uro-neurophysiological tests are elective procedures and should only be carried out in	4	С
specialised settings.		

*Upgraded based on panel consensus.

3.3.8 Renal function

In many patients with neuro-urological disorders, the UUT is at risk, particularly in patients who develop high detrusor pressure during the filling phase. Although effective treatment can reduce this risk, there is still a relatively high incidence of renal morbidity [115]. Patients with SCI or SB have a substantially higher risk of developing renal failure compared with patients with slowly progressive non-traumatic neurological disorders, such as MS and Parkinson's disease (PD) [116].

Caregivers must be informed of this risk and instructed to watch carefully for any signs or symptoms of a possible deterioration in the patient's renal function. There are no high level evidence publications available which show the optimal management to preserve renal function in these patients [117].

3.4 Disease management

3.4.1 Introduction

The primary aims for treatment of neuro-urological symptoms, and their priorities, are [118, 119]:

- protection of the UUT;
- achievement (or maintenance) of urinary continence;
- restoration of the LUT function;
- improvement of the patient's QoL.

Further considerations are the patient's disability, cost-effectiveness, technical complexity and possible complications [119].

Renal failure is the main mortality factor in SCI patients who survive the trauma [120, 121]. Keeping the detrusor pressure during both the filling and voiding phases within safe limits significantly reduces the mortality from urological causes in these patients [122-124] and has consequently become the top priority in the treatment of patients with neuro-urological symptoms [118, 119].

In patients with high detrusor pressure during the filling phase (DO, low bladder compliance), treatment is aimed primarily at conversion of an overactive, high-pressure bladder into a low-pressure reservoir despite the resulting residual urine [118]. Reduction of the detrusor pressure contributes to urinary continence, and consequently to social rehabilitation and QoL. It is also pivotal in preventing UTIs [125, 126]. Complete continence, however, cannot always be obtained.

3.4.2 Non-invasive conservative treatment

3.4.2.1 Assisted bladder emptying - Credé manoeuvre, Valsalva manoeuvre, triggered reflex voiding Incomplete bladder emptying is a serious risk factor for UTI, high intravesical pressure during the filling phase, and incontinence. Methods to improve the voiding process are therefore practiced.

Bladder expression (Credé manoeuvre) and voiding by abdominal straining (Valsalva manoeuvre): The downwards movement of the lower abdomen by suprapubic compression (Credé) or by abdominal straining (Valsalva) leads to an increase in intravesical pressure, and generally also causes a reflex sphincter contraction [127, 128]. The latter may increase bladder outlet resistance and lead to inefficient emptying. The high pressures created during these procedures are hazardous for the urinary tract [129, 130]. Therefore, their use should be discouraged unless urodynamics show that the intravesical pressure remains within safe limits [119].

Long-term complications are unavoidable for both methods of bladder emptying [128]. The already weak pelvic floor function may be further impaired, thus introducing or exacerbating already existing stress urinary incontinence (SUI) [130].

Triggered reflex voiding: Stimulation of the sacral or lumbar dermatomes in patients with UMNL can elicit a reflex detrusor contraction [130]. The risk of high pressure voiding is present and interventions to decrease outlet resistance may be necessary [131]. Triggering can induce AD, especially in patients with high level SCI (at or above Th 6) [132]. All assisted bladder emptying techniques require low outlet resistance. Even then, high detrusor pressures may still be present. Hence, patients need dedicated education and close urodynamic and urological surveillance [130, 133-135].

Note: In the literature, including some of the references cited here, the concept "reflex voiding" is sometimes used to cover all three assisted voiding techniques described in this section.

External appliances: Social continence may be achieved by collecting urine during incontinence, for instance using pads [119]. Condom catheters with urine collection devices are a practical method for men [119]. The infection risk must be closely observed [119]. The penile clamp is absolutely contraindicated in case of DO or low bladder compliance because of the risk of developing high intravesical pressure and pressure sores/ necrosis in cases of altered/absent sensations.

3.4.2.2 Neuro-urological rehabilitation

3.4.2.2.1 Bladder rehabilitation including electrical stimulation

The term bladder rehabilitation summarises treatment options that aim to re-establish bladder function in patients with neuro-urological symptoms. Strong contraction of the urethral sphincter and/or pelvic floor, as well as anal dilatation, manipulation of the genital region, and physical activity inhibit micturition in a reflex manner [119, 136]. The first mechanism is affected by activation of efferent nerve fibres, and the latter ones are produced by activation of afferent fibres [98]. Electrical stimulation of the pudendal nerve afferents strongly inhibits the micturition reflex and detrusor contraction [137]. This stimulation might then support the restoration of the balance between excitatory and inhibitory inputs at the spinal or supraspinal level [119, 138]. Evidence for bladder rehabilitation using electrical stimulation in neurological patients is mainly based on small non-comparative studies with high risk of bias.

Peripheral temporary electrostimulation: Tibial nerve stimulation and transcutaneous electrical nerve stimulation might be effective and safe for treating neurogenic lower urinary tract dysfunction, but more reliable evidence from well-designed RCTs is required to reach definitive conclusions [138, 139].

Peripheral temporary electrostimulation combined with pelvic floor muscle training and biofeedback: In MS patients, combining active neuromuscular electrical stimulation with pelvic floor muscle training and EMG biofeedback can achieve a substantial reduction of neuro-urological symptoms [140]. This treatment combination seems to be more effective than either therapy alone [141, 142].

Intravesical electrostimulation: Intravesical electrostimulation can increase bladder capacity and improve bladder compliance and bladder filling sensation in patients with incomplete SCI or myelomeningocele (MMC) [143]. In patients with neurogenic detrusor underactivity, intravesical electrostimulation may also improve voiding and reduce residual volume [144, 145].

Repetitive transcranial magnetic stimulation: Although improvement of neuro-urological symptoms has been described in PD and MS patients, this technique is still under investigation [146, 147].

Summary: To date, bladder rehabilitation techniques are mainly based on electrical or magnetic stimulation. However, there is a lack of well-designed studies.

3.4.2.3 Drug treatment

A single, optimal, medical therapy for neuro-urological symptoms is not yet available. Commonly, a combination of different therapies (e.g. intermittent catheterisation and antimuscarinic drugs) is advised to prevent urinary tract damage and improve long-term outcomes, particularly in patients with a suprasacral SCI or MS [130, 148-150].

3.4.2.3.1 Drugs for storage symptoms

Antimuscarinic drugs: They are the first-line choice for treating NDO, increasing bladder capacity and

reducing episodes of UI secondary to NDO by the inhibition of parasympathetic pathways [119, 151-157]. Antimuscarinic drugs have been used for many years to treat patients with NDO [154, 155, 158], and the responses of individual patients to antimuscarinic treatment are variable. Despite a meta-analysis confirming the clinical and urodynamic efficacy of antimuscarinic therapy compared to placebo in adult NDO, a more recent integrative review has indicated that the information provided is still too limited for clinicians to be able to match trial data to the needs of individual patients with SCI mainly because of the lack of standardised clinical evaluation tools such as the ASIA, bladder diary and validated symptoms score. [155, 159].

Higher doses or a combination of antimuscarinic agents may be an option to maximise outcomes in neurological patients [156, 157, 160-163]. However, these drugs have a high incidence of adverse events, which may lead to early discontinuation of therapy [155, 156].

Choice of antimuscarinic agent: Oxybutynin [119, 154-157, 164], trospium [155, 162, 165], tolterodine [166] and propiverine [155, 167] are established, effective and well tolerated treatments even in long-term use [154, 155, 168, 169]. Darifenacin [170, 171] and solifenacin [169, 172] have been evaluated in NDO secondary to SCI and MS [155, 170, 171, 173] with results similar to other antimuscarinic drugs. A pilot study using solifenacin in NDO due to PD showed an improvement in UI [174]. The relatively new drug, fesoterodine, an active metabolite of tolterodine, has also been introduced, even though to date there has been no published clinical evidence of its use in the treatment of neuro-urological disorders. Favourable results with the new drug imidafenacin have been reported [175].

Side effects: Controlled-release antimuscarinics have some minor side effects, e.g. dry mouth [176, 177]. It has been suggested that different ways of administration may help to reduce side effects. Moreover, imidafenacine has been safely used in neurological patients with no worsening of cognitive function [175].

Other agents

Beta-3-adrenergic receptor agonists have recently been introduced and evaluated in OAB, but clinical experience in neuro-urological patients is limited [178]. Studies on safety and effectiveness in NDO are ongoing [179]. Depending on the results of these studies, combined therapy with antimuscarinics may be an attractive option [180].

3.4.2.3.2 Drugs for voiding symptoms

Detrusor underactivity: Cholinergic drugs, such as bethanechol and distigmine, have been considered to enhance detrusor contractility and promote bladder emptying, but are not frequently used in clinical practice [181]. Only preclinical studies have documented the potential benefits of cannabinoid agonists on improving detrusor contractility when administered intravesically [182, 183]. Conversely, RCTs on the use of nabixinols, D-9-tetrahydrocannabinol or oral cannabis extract did not report any significant reduction of incontinence episodes in MS patients [184].

Decreasing bladder outlet resistance: α-blockers (e.g. tamsulosin, naftopidil and silodosin) seem to be effective for decreasing bladder outlet resistance, post-void residual and AD [185-187].

Increasing bladder outlet resistance: Several drugs have shown efficacy in selected cases of mild SUI, but there are no high-level evidence studies in neurological patients [119].

3.4.2.4 Recommendations for drug treatments

Recommendations	LE	GR
Use antimuscarinic therapy as the first-line medical treatment for neurogenic detrusor	1a	А
overactivity.		
Alternative routes of administration (i.e., transdermal or intravesical) of antimuscarinic agents	2	А
may be used.		
Maximise outcomes for neurogenic detrusor overactivity by considering a combination of	3	В
antimuscarinic agents.		
Prescribe α -blockers to decrease bladder outlet resistance.	1b	А
Do not prescribe parasympathomimetics for underactive detrusor.	1a	A
Do not prescribe drug treatment in neurogenic stress urinary incontinence.	4	A*
411 1 1 1 1		

*Upgraded based on panel consensus.

3.4.2.5 Minimally invasive treatment

3.4.2.5.1 Catheterisation

Intermittent self- or third-party catheterisation [188, 189] is the preferred management for neuro-urological patients who cannot effectively empty their bladders [119]. Sterile IC, as originally proposed by Guttmann and Frankel [188], significantly reduces the risk of UTI and bacteriuria [119, 190, 191], compared with clean IC introduced by Lapides *et al.* [189]. However, it has not yet been established whether or not the incidence of UTI, other complications and user satisfaction are affected by either sterile or clean IC, coated or uncoated catheters or by any other strategy.

Sterile IC cannot be considered a routine procedure [119, 191]. Aseptic IC is an alternative to sterile IC [192].

Contributing factors to contamination are insufficient patient education and the inherently greater risk of UTI in neuro-urological patients [119, 193-197]. The average frequency of catheterisations per day is four to six times [198] and the catheter size most often used is between 12-16 Fr. In aseptic IC, an optimum frequency of five times showed a reduction of UTI [198]. Ideally, bladder volume at catheterisation should, as a rule, not exceed 400-500 mL.

Indwelling transurethral catheterisation and, to a lesser extent, suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI [119, 199-207]. Therefore, both procedures should be avoided, when possible. Silicone catheters are preferred as they are less susceptible to encrustation and because of the high incidence of latex allergy in the neuro-urological patient population [208].

3.4.2.5.2 Recommendations for catheterisation

Recommendations	LE	GR
Use intermittent catheterisation, whenever possible aseptic technique, as a standard treatment	3	А
for patients who are unable to empty their bladder.		
Thoroughly instruct patients in the technique and risks of intermittent catheterisation.	3	А
Use a catheter size between 12-16 Fr.	4	B*
Avoid indwelling transurethral and suprapubic catheterisation whenever possible.	3	А
*Upgraded based on panel consensus.		

3.4.2.5.3 Intravesical drug treatment

To reduce DO, antimuscarinics can also be administered intravesically [209-213]. The efficacy, safety and tolerability of intravesical administration of 0.1% oxybutynin hydrochloride compared to its oral administration for treatment of NDO has been demonstrated in a recent randomised controlled study [213]. This approach may reduce adverse effects due to the fact that the antimuscarinic drug is metabolised differently [210] and a greater amount is sequestered in the bladder, even more than with electromotive administration [209].

The vanilloids, capsaicin and resiniferatoxin, desensitise the C-fibres and thereby decrease DO, for a period of a few months, until the sensation of these fibres has been restored [214-216]. The dosage is 1-2 mMol capsaicin in 100 mL 30% alcohol, or 10-100 nMol resiniferatoxin in 100 mL 10% alcohol for 30 minutes. Resiniferatoxin has about a 1,000-fold potency compared to capsaicin, with less pain during the instillation, and is effective in a patient refractory to capsaicin. Clinical studies have shown that resiniferatoxin has limited clinical efficacy compared to botulinum toxin A (BTX-A) injections in the detrusor [215]. Currently, there is no indication for the use of these substances, which are not licensed for intravesical treatment.

3.4.2.5.4 Botulinum toxin injections in the bladder

Botulinum toxin A causes a long-lasting but reversible chemical denervation that lasts for about nine months [217, 218]. The toxin injections are mapped over the detrusor in a dosage that depends on the preparation used. Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS or SCI in phase III RCTs [219, 220] and systematic reviews [221, 222]. Repeated injections seem to be possible without loss of efficacy [217, 223, 224]. The most frequent side effects are UTIs and elevated PVR [220, 223]. Intermittent catheterisation may become necessary. Rare but severe adverse events include AD and respiratory problems. Generalised muscular weakness may occur [217, 220, 224].

3.4.2.5.5 Bladder neck and urethral procedures

Reduction of the bladder outlet resistance may be necessary to protect the UUT. This can be achieved by chemical denervation of the sphincter or by surgical interventions (bladder neck or sphincter incision or urethral stent). Incontinence may result and can be managed by external devices (see Section 3.4.2.1).

Botulinum toxin A: This can be used to treat DSD effectively by injection at a dose that depends on the preparation used. The dyssynergia is abolished for a few months, necessitating repeat injections. The efficacy of this treatment has been reported to be high and with few adverse effects [225-227]. However, a recent Cochrane report concluded that because of limited evidence future RCTs assessing the effectiveness of BTX-A injections also need to address the uncertainty about the optimal dose and mode of injection [228]. In addition, this therapy is not licensed.

Balloon dilatation: Favourable immediate results were reported [229], but there have been no further reports since 1994 therefore, this method is no longer recommended.

Sphincterotomy: By staged incision, bladder outlet resistance can be reduced without completely losing the closure function of the urethra [118, 119, 219]. Different techniques are used, and laser treatment appears to be advantageous [230, 231]. Sphincterotomy needs to be repeated at regular intervals in many patients [232], but it is efficient and does not cause severe adverse effects [118, 229]. Secondary narrowing of the bladder neck may occur, for which combined bladder neck incision might be considered [233].

Bladder neck incision: This is indicated only for secondary changes at the bladder neck (fibrosis) [118, 230]. This procedure is not recommended in patients with detrusor hypertrophy, which causes thickening of the bladder neck [118].

Stents: Implantation of urethral stents results in continence being dependent on adequate closure of the bladder neck [119]. The results are comparable with sphincterotomy and the stenting procedure has a shorter duration of surgery and hospital stay [234, 235]. However, the costs [118], possible complications and re-interventions [236, 237] are limiting factors in their use [238-241].

Increasing bladder outlet resistance: This can improve the continence condition. Despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with neuro-urological disorders [119, 242, 243].

Urethral inserts: Urethral plugs or valves for the management of (female) stress incontinence have not been applied in neuro-urological patients. The experience with active pumping urethral prosthesis for treatment of the underactive or acontractile detrusor were disappointing [244].

3.4.2.5.6 Recommendations for minimal invasive treatment*

	GR
	А
	В

*Recommendations for catheterisation are listed separately under Section 3.4.2.5.2.

3.4.3 Surgical treatment

3.4.3.1 Bladder neck and urethral procedures

Increasing the bladder outlet resistance has the inherent risk of causing high intravesical pressure. Procedures to treat sphincteric incontinence are therefore suitable only when the detrusor activity can be controlled and when no significant reflux is present. A simultaneous bladder augmentation and IC may be necessary [119].

Urethral sling: Various materials have been used for this procedure with enduring positive results. The procedure is established in women with the ability to self-catheterise [119, 245-250]. There is growing evidence that synthetic slings can be used effectively with acceptable medium to long-term results and minimal morbidity in neurological patients [251, 252]. Besides the pubovaginal sling, which has been considered the procedure of choice in this subgroup of patients, recent reports suggest that both the transobturator and the retropubic approaches may also be considered, with similar failure rates and a reduction in the need for IC. However, for both approaches a higher incidence of de novo urgency was reported [252, 253]. In men, both autologous and synthetic slings may also be an alternative [251, 252, 254-256].

Artificial urinary sphincter: This device was introduced by Light and Scott [257] for patients with neurourological disorders [119]. It has stood the test of time and acceptable long-term outcomes can be obtained [258-263]. *Functional sphincter augmentation*: Transposing the gracilis muscle to the bladder neck [264] or proximal urethra [265], can enable the possible creation of a functional autologous sphincter by electrical stimulation [264-266]. Therefore, raising the prospect of restoring control over the urethral closure.

Bladder neck and urethra reconstruction: The classical Young-Dees-Leadbetter procedure [267] for bladder neck reconstruction in children with bladder exstrophy, and Kropp urethra lengthening [268] improved by Salle [269], are established methods to restore continence provided that IC is practiced and/or bladder augmentation is performed [119, 270].

Urethral inserts: See section 3.4.2.5.5.

3.4.3.2 Denervation, deafferentation, sacral neuromodulation

Sacral rhizotomy, also known as sacral deafferentation, has achieved some success in reducing DO [271-273], but nowadays, it is used mostly as an adjuvant to sacral anterior root stimulation (SARS) [274-278]. Alternatives to rhizotomy are sought in this treatment combination [279-281].

Sacral anterior root stimulation is aimed at producing detrusor contraction. The technique was developed by Brindley [282] and is only applicable to complete lesions above the implant location, as its stimulation amplitude is over the pain threshold. The urethral sphincter efferents are also stimulated, but because the striated muscle relaxes faster than the smooth muscle of the detrusor, so-called "post-stimulus voiding" occurs. This approach has been successful in highly selected patients [275, 283, 284]. By changing the stimulation parameters, this method can also induce defecation or erection. A recent study reports that Charcot spinal arthropathy should be considered as a potential long-term complication of SARS, leading to spinal instability and to SARS dysfunction [285].

Sacral neuromodulation [286] might be effective and safe for treating neuro-urological symptoms, but there is a lack of RCTs and it is unclear which neurological patients are most suitable [287-290].

3.4.3.3 Bladder covering by striated muscle

When the bladder is covered by striated muscle that can be stimulated electrically, or ideally that can be contracted voluntarily, voiding function can be restored to an acontractile bladder. The rectus abdominis [291] and latissimus dorsi [292] have been used successfully in patients with neuro-urological symptoms [293, 294].

3.4.3.4 Bladder augmentation

The aim of auto-augmentation (detrusor myectomy) is to reduce DO or improve low bladder compliance. The advantages are: low surgical burden, low rate of long-term adverse effects, positive effect on patient QoL, and it does not preclude further interventions [118, 119, 295-301].

Replacing or expanding the bladder by intestine or other passive expandable coverage will improve bladder compliance and at least reduce the pressure effect of DO [302, 303]. Inherent complications associated with these procedures are: recurrent infection, stone formation, perforation or diverticula, possible malignant changes, and for the intestine, metabolic abnormality, mucus production and impaired bowel function [119, 304-306]. The procedure should be used with caution in patients with neuro-urological symptoms, but may become necessary if all less-invasive treatment methods have failed. Special attention should be paid to patients with pre-operative renal scars since metabolic acidosis can develop [307].

Bladder augmentation is a valid option to decrease detrusor pressure and increase bladder capacity, whenever more conservative approaches have failed. Several different techniques have been published, with comparable and satisfactory results [297, 308-316]. Bladder substitution, even by performing a supratrigonal cystectomy [317], to create a low-pressure reservoir is indicated in patients with a severely thick and fibrotic bladder wall [119]. Intermittent catheterisation may become necessary after this procedure. A significant improvement in QoL has been reported, probably related to the perception of better health and the resolution/improvement of urinary incontinence [318].

3.4.3.5 Urinary diversion

When no other therapy is successful, urinary diversion must be considered for the protection of the UUT and for the patient's QoL [119].

Continent diversion: This should be the first choice for urinary diversion. Patients with limited dexterity may prefer a stoma instead of using the urethra for catheterisation. A continent stoma can be created using various techniques. However, all of them have frequent complications, including leakage or stenosis. The short-term continence rates are > 80% and good protection of the UUT is achieved [119, 319-331]. For cosmetic reasons, the umbilicus is often used for the stoma site [326, 329, 330, 332-334].

Incontinent diversion: If catheterisation is impossible, incontinent diversion with a urine-collecting device is indicated. Ultimately, it could be considered in patients who are wheelchair bound or bed-ridden with intractable and untreatable incontinence, in patients with LUT destruction, when the UUT is severely compromised, and in patients who refuse other therapy [119]. An ileal segment is used for the deviation in most cases [119, 335-338]. Patients gain better functional status and QoL after surgery [339].

Undiversion: Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of detrusor pressure and incontinence [119]. The patient must be carefully counselled and must comply meticulously with the instructions [119]. Successful undiversion can then be performed [340].

3.4.3.6 Recommendations for surgical treatment

Recommendations	LE	GR
Perform bladder augmentation in order to treat refractory neurogenic detrusor overactivity.	3	А
Place an autologous urethral sling in female patients with neurogenic stress urinary	4	B*
incontinence who are able to self-catheterise.		
Insert an artificial urinary sphincter in male patients with neurogenic stress urinary	3	A
incontinence.

3.5 Urinary tract infection in neuro-urological patients

3.5.1 Epidemiology, aetiology and pathophysiology

Urinary tract infection is the onset of signs and/or symptoms accompanied by laboratory findings of a UTI (bacteriuria, leukocyturia and positive urine culture) [332]. There are no evidence-based cut-off values for the quantification of these findings. The published consensus is that a significant bacteriuria in persons performing IC is present with $> 10^2$ cfu/mL, $> 10^4$ cfu/mL in clean-void specimens and any detectable concentration in suprapubic aspirates. Regarding leukocyturia, 10 or more leukocytes in centrifuged urine samples per microscopic field (400x) are regarded as significant [332].

The pathogenesis of UTI in neuro-urological patients is multifactorial. Male gender seems to be a risk factor for febrile UTI [341]. Several etiological factors have been described: altered intrinsic defence mechanisms, impaired washout and catheterisation [342]. The exact working mechanisms, however, still remain unknown. The presence of asymptomatic bacteriuria in SCI patients is higher than in the general population, and varies depending on bladder management. Prevalence of bacteriuria in those performing clean IC varies from 23-89% [343]. Sphincterotomy and condom catheter drainage has a 57% prevalence [344]. Asymptomatic bacteria should not be routinely screened for in this population [345].

Individuals with neuro-urological symptoms, especially those with SCI, may have other signs and symptoms in addition to or instead of traditional signs and symptoms of a UTI in able-bodied individuals. Other problems, such as AD, may develop or worsen due to a UTI [346]. The most common signs and symptoms suspicious of a UTI in those with neuro-urological disorders are fever, new onset or increase in incontinence, including leaking around an indwelling catheter, increased spasticity, malaise, lethargy or sense of unease, cloudy urine with increased urine odour, discomfort or pain over the kidney or bladder, dysuria, or AD [346, 347].

3.5.2 **Diagnostic evaluation**

The gold standard for diagnosis is urine culture and urinalysis. A dipstick test may be more useful to exclude than to prove UTI [348, 349]. As bacterial strains and resistance patterns in persons with neuro-urological disorders may differ from those of able-bodied patients, microbiologic testing is mandatory [350].

3.5.3 Disease management

Bacteriuria in patients with neuro-urological disorders should not be treated. Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving the outcome [351]. Urinary tract infections in persons with neuro-urological disorders are by definition a complicated UTI. Therefore, single-dose treatment is not advised. There is no consensus in the literature about the duration of treatment, it depends on the severity of the UTI and the involvement of kidneys and the prostate. Generally, a five to seven day course of antibiotic treatment is advised, which can be extended up to fourteen days according to the extent of the infection [351]. The choice of antibiotic therapy should be based on the results of the microbiologic testing. If immediate treatment is mandatory (e.g. fever, septicaemia, intolerable clinical

symptoms, extensive AD), the choice of treatment should be based on local and individual resistance profiles [352].

3.5.3.1 Recurrent UTI

Recurrent UTI in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem, e.g. high bladder pressure during storage and voiding, incomplete voiding or bladder stones. The improvement of bladder function, by treating DO by BTX-A injection in the detrusor [353], and the removal of bladder stones or other direct supporting factors, especially indwelling catheters, as early as possible, are mandatory [350].

3.5.3.2 Prevention

If the improvement of bladder function and removal of foreign bodies/stones is not successful, additional UTI prevention strategies should be utilised. The use of hydrophilic catheters was associated with a lower rate of UTI in a recent meta-analysis [354]. Bladder irrigation has not been proven effective [355].

Various medical approaches have been tested for UTI prophylaxis in patients with neuro-urological disorders. The benefit of cranberry juice for the prevention of UTI could not be demonstrated in RCTs [356]. Methenamine hippurate is not effective in individuals with neuro-urological symptoms [357]. There is no sufficient evidence to support the use of L-methionine for urine acidification to prevent recurrent UTI [358]. There is only weak evidence that oral immunotherapy reduces bacteriuria in patients with SCI, and no evidence that recurrent UTIs are reduced [359]. Low-dose, long-term, antibiotic prophylaxis cannot reduce UTI frequency, but increases bacterial resistance and is therefore not recommended [351].

An application scheme of antibiotic substances for antibiotic prophylaxis provided long-term positive results, but the results of this trial need to be confirmed in further studies [360]. Another possible future option, the inoculation of apathogenic *Escherichia coli* strains into the bladder, has provided positive results in initial studies, but because of the paucity of data [361], cannot be recommended as a treatment option.

In summary, based on the criteria of evidence-based medicine, there is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations. Therefore, individualised concepts should be taken into consideration, including immunostimulation, phytotherapy and complementary medicine [362]. Prophylaxis in patients with neuro-urological disorders is important to pursue, but since there are no data favouring one approach over another, prophylaxis is essentially a trial and error approach.

3.5.4 **Recommendations for the treatment of UTI**

3.6 Sexual (dys)function and fertility

These Guidelines specifically focus on sexual dysfunction and infertility in patients with a neurological disease [363, 364]. Non-neurogenic, male sexual dysfunction and infertility are covered in separate EAU Guidelines [365, 366]. In neuro-urological patients sexual problems can be identified at three levels: primary (direct neurological damage), secondary (general physical disabilities) and tertiary (psychosocial and emotional issues) sexual dysfunction [367]. Adopting a systematic approach, such as the PLISSIT model (Permission, Limited Information, Specific Suggestions and Intensive Therapy) [368], provides a framework for counselling and treatment involving a stepwise approach to the management of neurogenic sexual dysfunction. Sexual dysfunction is associated with neurogenic lower urinary tract dysfunction in patients with MS [369] and spina bifida [370]. Although various patient-reported outcome measures (PROMs) are available to evaluate sexual function, the evidence for good PROMs is limited and studies with high methodological quality are needed [371].

3.6.1 Erectile dysfunction (ED)

3.6.1.1 Phosphodiesterase type 5 inhibitors (PDE5Is) Questions:

- What is the effectiveness of the various PDE5Is in the different neuro-urological patient groups?
- What common side-effects are described?

Evidence:

Phosphodiesterase type 5 inhibitors (PDE5Is) are recommended as first-line treatment in neurogenic erectile dysfunction (ED) [363, 372]. In SCI patients, tadalafil, vardenafil and sildenafil have all improved retrograde ejaculation and improved erectile function and satisfaction on IIEF-15. Tadalafil 10 mg was shown to be more effective than sildenafil 50 mg. All currently available PDE5Is appear to be effective and safe, although there are no high level evidence studies in neuro-urological patients investigating the efficacy and side effects across different PDE5Is, dosages and formulations [373].

For MS patients two studies reported significant improvement in ED when using sildenafil and tadalafil. One study, however, showed no improvement in ED with sildenafil.

In PD normal erectile function was described in over half of the patients using sildenafil 100 mg and a significant improvement in IIEF-15 score was found compared to placebo. While most neuro-urological patients require long-term therapy for ED some have a low compliance rate or stop therapy because of side effects [374, 375], most commonly headache and flushing [372]. In addition, PDE5Is may induce relevant hypotension in patients with tetraplegia/high-level paraplegia and multiple system atrophy [374, 375]. As a prerequisite for successful PDE5I-therapy, some residual nerve function is required to induce erection. Since many patients with SCI use on-demand nitrates for the treatment of AD, they must be counselled that PDE5Is are contraindicated when using nitrate medication.

3.6.1.2 Drug therapy other than PDE5Is

Fampridine to treat neurogenic spasticity has been shown to be beneficial in improving ED in two domains of the IIEF-15 in SCI and MS patients, however, with a significant discontinuation rate due to severe adverse events [376]. Sublingual apomorfine was shown to have poor results on ED in SCI patients and side-effects in half of the patients [377]. In PD pergolide mesylate showed a significant improvement in IIEF-15 scores up to twelve months follow-up [378].

3.6.1.3 Mechanical devices

Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular [379-383].

3.6.1.4 Intracavernous injections and intraurethral application

Patients not responding to oral drugs may be offered intracavernous injections (alprostadil, papaverine and phentolamine) that have been shown to be effective in a number of neurological conditions, including SCI, MS, and diabetes mellitus [384-390] but their use requires careful dose titration and some precautions. Complications of intracavernous drugs include pain, priapism and corpora cavernosa fibrosis.

Intracavernous vasoactive drug injection is the first-line therapeutic option in patients taking nitrate medications, as well as those with concerns about drug interactions with PDE5Is, or in whom PDE5Is are ineffective. The impact of intracavernous injections on ejaculation and orgasmic function, their early use for increasing the recovery rate of a spontaneous erection, and their effectiveness and tolerability in the long-term are unclear [374]. Intraurethral alprostadil application is an alternative but a less effective route of administration [390, 391].

3.6.1.5 Sacral neuromodulation

Sacral neuromodulation for LUT dysfunction may improve sexual function but high level evidence studies are lacking [372].

3.6.1.6 Penile prostheses

Penile prostheses may be considered for treatment of neurogenic ED when all conservative treatments have failed. At a mean follow-up of seven years 83.7% of patients with SCI were able to have sexual intercourse [372]. Serious complications, including infection and prosthesis perforation, may occur in about 10% of patients, depending on implant type [392-394].

3.6.1.7 Recommendations for erectile dysfunction

LE	GR
1b	А
3	А
3	В
4	B*
	LE 1b 3 3 4

*Upgraded based on panel consensus.

3.6.2 Male fertility

Male fertility can be compromised in the neurological patient by ED, ejaculation disorder, impaired sperm quality or various combinations of these three disorders. Among the major conditions contributing to neurogenic infertility are pelvic and retroperitoneal surgery, diabetes mellitus, SB, MS and SCI [395]. Erectile dysfunction is managed as described previously. Retrograde ejaculation may be reversed by sympathomimetic agents contracting the bladder neck, including imipramine, ephedrine, pseudoephedrine, and phenylpropanolamine [395]. The use of a balloon catheter to obstruct the bladder neck may be effective in obtaining antegrade ejaculation [396]. If antegrade ejaculation is not achieved, the harvest of semen from the urine may be considered [397].

Prostatic massage is safe and easy to use for obtaining semen in men with lesions above Th 10 [398]. In several patients, vibrostimulation or transrectal electroejaculation are needed for sperm retrieval [390, 395, 399, 400]. Semen retrieval is more likely with vibrostimulation in men with lesions above Th 10 [401-403]. In men with SCI, especially at or above Th 6, AD might occur during sexual activity and ejaculation [404, 405]; patients at risk and fertility clinics must be informed and aware of this potentially life-threatening condition. In SCI patients the use of oral midodrine can improve sperm retrieval at vibrostimulation [406].

In men with MS, use of disease modifying drugs during the conception phase, has not been associated with altered pregnancy outcomes [407]. Surgical procedures, such as, microsurgical epididymal sperm aspiration (MESA) or testicular sperm extraction (TESE), may be used if vibrostimulation and electroejaculation are not successful [408, 409]. Pregnancy rates in patients with SCI are lower than in the general population, but since the introduction of intracytoplasmic sperm injection (ICSI), men with SCI now have a good chance of becoming biological fathers [410-412].

3.6.2.1 Sperm quality and motility

The following has been reported on sperm quality and motility:

- bladder management with clean IC may improve semen quality compared to indwelling catheterisation, reflex voiding or bladder expression [413];
- in SCI patients sperm quality decreases at the early post traumatic phase demonstrating lower spermatozoid vitality (necrospermia), reduced motility (asthenospermia) and leucospermia [408];
- long-term valproate treatment for epilepsy negatively influences sperm count and motility [414];
- vibrostimulation produces samples with better sperm motility than electrostimulation [415, 416];
- electroejaculation with interrupted current produces better sperm motility than continuous current [417];
- freezing of sperm is unlikely to improve fertility rates in men with SCI [418].

Recommendations	LE	GR
Perform vibrostimulation and transrectal electroejaculation for sperm retrieval in men with	3	В
spinal cord injury.		
Perform microsurgical epididymal sperm aspiration, testicular sperm extraction and	3	В
intracytoplasmic sperm injection after failed vibrostimulation and/or transrectal		
electroejaculation in men with spinal cord injury.		
Counsel men with spinal cord injury at or above Th 6 and fertility clinics about the potentially	3	A*
life-threatening condition of autonomic dysreflexia.		
*Upgraded based on panel consensus.		

3.6.2.2 Recommendations for male fertility

3.6.3 Female sexuality

The most relevant publications on neurogenic female sexual dysfunction are in women with SCI and MS. After SCI, about 65-80% of women continue to be sexually active, but to a much lesser extent than before the injury, and about 25% report a decreased satisfaction with their sexual life [419-421]. Although sexual dysfunction is very common in women with MS, it is still often overlooked by medical professionals [422, 423].

The greatest physical barrier to sexual activity is UI. A correlation has been found between the urodynamic outcomes of low bladder capacity, compliance and high maximum detrusor pressure and sexual dysfunction in MS patients. Problems with positioning and spasticity affect mainly tetraplegic patients. Peer support may help to optimise the sexual adjustment of women with SCI in achieving a more positive self-image, self-esteem and feelings of being attractive to themselves and others [419, 424-426].

The use of specific drugs for sexual dysfunction is indicated to treat inadequate lubrication. Data on sildenafil for treating female sexual dysfunction are poor and controversial [427]. Although good evidence exists that psychological interventions are effective in the treatment of female hypoactive sexual desire disorder and female orgasmic disorder [428], there is a lack of high-evidence level studies in the neurological population.

Neurophysiological studies have shown that women with the ability to perceive Th 11-L2 pin-prick sensations may have psychogenic genital vasocongestion. Reflex lubrication and orgasm is more prevalent in women with SCI who have preserved the sacral reflex arc (S2-S5), even when it has not been shown in an individual woman that a specific level and degree of lesion is the cause of a particular sexual dysfunction. In SCI women with a complete lesion of the sacral reflex, arousal and orgasm may be evoked through stimulation of other erogenous zones above the level of lesions [429-431].

Sacral neuromodulation for LUT dysfunction may improve sexual function but high-evidence studies are lacking [427].

Women with SCI reported dissatisfaction with the quality and quantity of sexuality-related rehabilitation services and were less likely to receive sexual information than men [429, 432, 433].

3.6.3.1 Recommendation for female sexuality

Recommendation	LE	GR
Do not offer medical therapy for the treatment of neurogenic sexual dysfunction in women.	4	A*
*Upgraded based on panel consensus.		

3.6.4 Female fertility

There are few studies on female fertility in neurological patients. More than a third (38%) of women with epilepsy had infertility and the relevant predictors were exposure to multiple (three or more) antiepileptic drugs, older age and lower education [434].

Although it seems that the reproductive capacity of women with SCI is only temporarily affected by SCI with cessation of menstruation for approximately six months after SCI [435], there are no high-evidence level studies. About 70% of sexually active women use some form of contraception after injury, but fewer women use the birth control pill compared to before their injury [436].

Women with SCI are more likely to suffer complications during pregnancy, labour and delivery compared to able-bodied women. Complications of labour and delivery include bladder problems, spasticity, pressure sores, anaemia, and AD [437, 438]. Obstetric outcomes include higher rates of Caesarean sections and an increased incidence of low birth-weight babies [436].

Epidural anaesthesia is chosen and effective for most patients with AD during labour and delivery [439, 440].

There is very little published data on women's experience of the menopause following SCI [441]. Women with MS who plan a pregnancy should evaluate their current drug treatment with their treating physician [442]. Clinical management should be individualised to optimise both the mother's reproductive outcomes and MS course [443].

3.6.4.1 Recommendation for female fertility

Recommendation	LE	GR
Take a multidisciplinary approach, tailored to individual patient's needs and preferences, in the	4	A*
management of fertility, pregnancy and delivery in women with neurological diseases.		
*Upgraded based on panel consensus.		

3.7 Follow-up

3.7.1 Introduction

Neuro-urological disorders are often unstable and the symptoms may vary considerably, even within a relatively short period. Regular follow-up is therefore necessary [117].

Depending on the type of the underlying neurological pathology and the current stability of the neuro-urological symptoms, the interval between initial investigations and control diagnostics may vary and in many cases should not exceed one to two years. In high-risk neuro-urological patients this interval should be much shorter. Urinalysis should be performed regularly; the frequency to be guided by patient symptoms. The UUT should be checked by ultrasonography at regular intervals in high-risk patients; about once every six months. In these patients, physical examination and urine laboratory should take place every year. Any significant clinical change warrants further, specialised, investigation. However, there is a complete lack of high level evidence studies on this topic and every recommendation must be viewed critically in each individual neuro-urological patient [117].

In addition, bladder wall thickness can be measured on ultrasonography as an additional risk assessment for upper tract damage [444], although a 'safe' cut-off threshold for this has not been agreed [445]. The utility of DMSA for follow-up of neuro-urological patients has not been fully evaluated [446].

3.7.2 Recommendations for follow-up

Recommendations	LE	GR
Assess the upper urinary tract at regular intervals in high risk patients.	4	A*
Preform a physical examination and urine laboratory every year in high risk patients.	4	A*
Any significant clinical changes should instigate further, specialised, investigation.	4	A*
Preform urodynamic investigation as a mandatory baseline diagnostic intervention in high-risk	3	А
patients at regular intervals.		

*Upgraded based on panel consensus.

3.8 Conclusions

Neuro-urological disorders have a multi-faceted pathology. They require an extensive and specific diagnosis before one can embark on an individualised therapy, which takes into account the medical and physical condition of the patient and the patient's expectations about their future. The urologist can select from a wealth of therapeutic options, each with its own pros and cons. Notwithstanding the success of any therapy embarked upon, close surveillance is necessary for the patient's entire life.

These Guidelines offer you expert advice on how to define the patient's neuro-urological symptoms as precisely as possible and how to select, together with the patient, the appropriate therapy. This last choice, as always, is governed by the golden rule: as effective as needed, as non-invasive as possible.

5. CONFLICT OF INTEREST

All members of the EAU Neuro-urology Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website: <u>http://www.uroweb.org/guidelines/</u>. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

EAU Guidelines on Erectile Dysfunction, Premature Ejaculation, Penile Curvature and Priapism

1. INTRODUCTION

1.1 Aim

These guidelines include four sections. The aim of the first two sections is to present the current evidence for the diagnosis and treatment of patients suffering from erectile dysfunction (ED) and premature ejaculation (PE). Erectile Dysfunction and PE are the two main complaints in male sexual medicine [1, 2]. Pharmacological therapies have completely changed the diagnostic and therapeutic approach to ED.

The aim of the third section is to provide the practicing urologist with the most recent evidence on the diagnosis and management of penile curvature in order to assist in their decision-making. Penile curvature is a common urological disorder which can be congenital or acquired. Congenital curvature is briefly discussed in these guidelines as a distinct pathology in the adult population without any other concomitant abnormality present (such as urethral abnormalities). For paediatric congenital penile curvature, please refer to the EAU Guidelines on Paediatric Urology, Chapter on Congenital Penile Curvature [3]. Acquired curvature is mainly due to Peyronie's disease but can also be due to the development of fibrosis following penile fracture.

The aim of the fourth section is to present the current evidence for the diagnosis and treatment of patients suffering from priapism. Priapism is a pathological condition representing a true disorder of penile erection that persists for more than four hours and beyond, or is unrelated to, sexual interest or stimulation [4]. Overall, erections lasting up to four hours are by consensus defined as 'prolonged'. Priapism may occur at all ages. The incidence rate of priapism in the general population is low (0.5-0.9 cases per 100,000 person-years) [5, 6]. In men with sickle cell disease, the prevalence of priapism is up to 3.6% in men less than eighteen years of age [7] increasing up to 42% in men more than eighteen years of age [8-11].

The Guidelines Office of the European Association of Urology (EAU) has appointed an Expert Panel to update previously published EAU guidelines for ED, PE, penile curvature and priapism.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guidelines recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not and should not purport to be a legal standard of care.

1.2 Publication history

The first EAU Guidelines on Erectile Dysfunction were published in 2000 with subsequent updates in 2001, 2002, 2004, 2005, 2009, 2013 and 2014. In particular, the 2009 document presented a significant update of the previous publication with the inclusion of the topic "Premature Ejaculation" and the text was renamed "EAU Guidelines on Male Sexual Dysfunction" [12]. In 2011 the Panel decided to develop new guidelines addressing Penile Curvature, which resulted in a new publication in 2012 [13]. In 2014 a guideline on Priapism was completed [14].

The 2016 edition merged the previous EAU guidelines for ED, PE, penile curvature and priapism into one guideline [15].

1.3 Available Publications

Alongside several scientific summaries published in the EAU scientific journal, European Urology [16-20], a quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the Male Sexual Dysfunction guidelines. These are abridged versions which may require consultation together with the full text version. All available material can be viewed and downloaded at the EAU website, which also includes a selection of translations produced by national urological associations: http://www.uroweb.org/guidelines/.

1.4 Panel composition

The EAU Guidelines Panel on Male Sexual Dysfunction consists of urologists. Members of this Panel have been selected based on their expertise to represent the professionals treating patients suffering from ED, PE, penile curvature and priapism.

2. METHODS

2.1 Introduction

References used in this text are assessed according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [21]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://www.uroweb.org/guidelines/</u>. A list of Associations endorsing the EAU Guidelines can also be reviewed online at the above address.

For the 2016 print, a scoping search was performed covering all areas of the guideline covering the period May 2015 to June 2016. Embase, Medline and the Cochrane Central Register of Controlled Trials (RCTs) databases were searched, with a limitation to systematic reviews, meta-analyses or randomised controlled trials. A total of 2,783 unique records were identified, retrieved and screened for relevance, of which 56 were selected for inclusion. A detailed search strategy is available online: <u>http://www.uroweb.org/guideline/male-sexual-dysfunction/</u>.

2.2 Review

This document was subject to peer review prior to publication in 2015.

2.3 Future goals

The results of ongoing and new systematic reviews will be included in the 2018 update of the Male Sexual Dysfuntion Guidelines. Ongoing systematic reviews include:

- 1. What is the effectiveness (efficacy and safety) of non-operative treatment for Peyronie's disease?
- 2. What is the effectiveness (efficacy and safety) of surgical treatment for Peyronie's disease?
- 3. What are the benefits and harms of testosterone treatment for male sexual dysfunction? [22].

3. MALE SEXUAL DYSFUNCTION

3.1 Erectile dysfunction

3.1.1 Epidemiology/aetiology/pathophysiology

Penile erection is a complex phenomenon which implies a delicate and co-ordinated equilibrium among the neurological, vascular and the tissue compartments. It includes arterial dilation, trabecular smooth muscle relaxation, and activation of the corporeal veno-occlusive mechanism [23]. Erectile Dysfunction is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance [24]. Erectile Dysfunction may affect physical and psychosocial health and may have a significant impact on the quality of life (QoL) of sufferers and their partners [25-27]. There is increasing evidence that ED can be an early manifestation of coronary artery and peripheral vascular disease. Erectile Dysfunction should not be regarded only as a Quality of Life (QoL), but also as a potential warning sign of cardiovascular disease (CVD) [28-30].

3.1.1.1 Epidemiology

Epidemiological data have shown a high prevalence and incidence of ED worldwide. Among others, the Massachusetts Male Aging Study (MMAS) [25] reported an overall prevalence of 52% ED in non-institutionalised men aged 40-70 years in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% [31]. The incidence rate of ED (new cases per 1,000 men annually) was 26 in the long-term data from the MMAS study [32] and 19.2 (mean follow-up of 4.2 years) in a Dutch study [33]. In a cross-sectional real-life study among men seeking first medical help for new-onset ED, one in four patients was younger than 40 years, with almost 50% of the young men complaining of severe ED [34]. Differences between these studies can be explained by differences in methodology, in the ages, and socio-economic and cultural status of the populations studied.

3.1.1.2 Risk factors

Erectile Dysfunction shares both unmodifiable and modifiable common risk factors with CVD (e.g., obesity, diabetes mellitus, dyslipidemia, metabolic syndrome, lack of exercise, and smoking) [27, 35-37]. Recent reports confirmed the association between ED status and age, diabetes mellitus duration, poor glycemic control and body mass index (BMI) [38].

A number of studies have shown some evidence that lifestyle modification [29, 39] and pharmacotherapy [39, 40] for CVD risk factors may be of help in improving sexual function in men with ED. However, it should be emphasised that more controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in the prevention or treatment of ED [30].

Epidemiological studies have also demonstrated consistent evidence for an association between lower urinary tract symptoms (LUTS)/benign prostatic hyperplasia (BPH) and sexual dysfunction, regardless of age, other comorbidities and various lifestyle factors [41]. The Multinational Survey on the Aging Male (MSAM-7) study - performed in the US, France, Germany, Italy, Netherlands, Spain, and the UK - systematically investigated the relationship between LUTS and sexual dysfunction in > 12,000 men aged 50-80 years. From the 83% of men who self-reported to be sexually active, the overall prevalence of LUTS was 90%, with the overall prevalence of ED being 49%, and a reported complete absence of erection in 10% of patients. Moreover, the overall prevalence of ejaculatory disorders was 46% [42].

The most recent epidemiological data collection have also highlighted other unexpected risk factors potentially associated with ED including psoriasis [43], ankylosing spondylitis [44], non-alcoholic fatty liver [45], and transrectal ultrasound (TRUS)-guided prostate biopsy [46].

3.1.1.3 Pathophysiology

The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 1) [23].

Vasculogenic
Cardiovascular disease (hypertension, coronary artery disease, peripheral vasculopathy, etc.)
Diabetes mellitus
Hyperlipidaemia
Smoking
Major pelvic surgery (radical prostatectomy (RP)) or radiotherapy (pelvis or retroperitoneum)
Neurogenic
Central causes
Degenerative disorders (multiple sclerosis, Parkinson's disease, multiple atrophy, etc.)
Spinal cord trauma or diseases
Stroke
Central nervous system tumours
Peripheral causes
Type 1 and 2 diabetes mellitus
Chronic renal failure
Polyneuropathy
Surgery (major surgery of pelvis/retroperitoneum)
Surgery of the urethra (urethral stricture, urethroplasty, etc.)
Anatomical or structural
Hypospadias, epispadias
Micropenis
Peyronie's disease
Penile cancer
Phimosis
Hormonal
Hypogonadism
Hyperprolactinaemia
Hyper- and hypothyroidism
Hyper- and hypocortisolism (Cushing's disease, etc.)
Panhypopituitarism and multiple endocrine disorders
Drug-induced
Antihypertensives (thiazide diuretics, etc.)
Antidepressants (selective serotonin reuptake inhibitors, tricyclics)

Table 1: Pathophysiology of ED

Antipsychotics (neuroleptics, etc.)
Antiandrogens (GnRH analogues and antagonists)
Recreational drugs (alcohol, heroin, cocaine, marijuana, methadone, synthetic drugs, anabolic steroids, etc.)
Psychogenic
Generalised type (e.g., lack of arousability and disorders of sexual intimacy)
Situational type (e.g., partner-related, performance-related issues or due to distress)
Trauma
Penile fracture
Pelvic fractures

3.1.1.3.1 Post-radical prostatectomy ED, post-radiotherapy ED & post-brachytherapy ED

Radical prostatectomy (RP) in any form (open, laparoscopic, or robotic) is a widely performed procedure for patients with clinically localised prostate cancer (PCa) and a life expectancy of at least ten years [47]. This procedure may lead to treatment-specific sequelae affecting health-related QoL. This outcome has become increasingly important with the more frequent diagnosis of PCa in younger men [48, 49]. Research has shown that 25-75% of men experience post-RP ED [50]. Of clinical relevance, the rate of unassisted post-operative erectile function recovery is in the range between 20 and 25% in most studies; (these rates emerged not to have been substantially improved or changed over the past seventeen years [51]. Given the growing clinical importance of robot-assisted RP (RARP), this type of surgery is becoming the paradigm for post-operative functional results. A systematic review (SR) has shown a significant advantage in favour of RARP in comparison with open retropubic RP in terms of 12-month potency rates [52], without significant differences between laparoscopic RP and RARP. Some recent reports confirm that the possibility of achieving erectile function recovery is about twice as high for the RARP compared with the open RP [53]. Recently a prospective, controlled, non-randomised trial of patients undergoing RP in fourteem Swedish centres comparing RARP versus retropubic RP, showed a small improvement regarding erectile function (EF) after RARP [54]. Conversely, a randomised controlled phase 3 study of men assigned to open RP or RARP showed that the two techniques yielded similar functional outcomes at twelve weeks [55]. As a whole, more controlled prospective studies, with longer term follow-up, are necessary to determine if RARP is superior to open RP in terms of post-operative ED rates [56]. Overall, patient age and surgical volume, with the consequent ability to preserve the neurovascular bundles, seem to be the main factors in promoting the highest rates of post-operative potency [48, 50].

Pre-operative potency is a major factor associated with the recovery of EF after surgery [49]. Patients being considered for nerve-sparing RP (NSRP) should ideally be potent pre-operatively [48, 49]. Overall, the chronological aspects are of major clinical importance in terms of post-operative recovery of erectile function. Available data confirm that post-operative erectile function recovery can also occur years following RP (up to 48 months) [57]. Likewise, it is shared opinion that the timing of post-operative therapy (any type) should be commenced as close as possible to the surgical procedure [48, 50].

Erectile Dysfunction is also a common sequela after external beam radiotherapy and brachytherapy for PCa [58, 59]. The mechanisms contributing to ED after prostate irradiation involve injury to the neurovascular bundles, penile vasculature, and cavernosal structural tissue [58]. Alternative treatments for PCa including cryotherapy and high-intensity focused ultrasound (HIFU) are also associated with equivalent or higher rates of ED compared to surgery or radiation therapy [60, 61].

3.1.1.3.2 Summary of evidence on the epidemiology/aetiology/pathophysiology of ED

Summary of evidence	LE
ED is common worldwide.	2b
ED shares common risk factors with cardiovascular disease.	2b
Lifestyle modification (regular exercise and decrease in body mass index) can improve erectile	1b
function.	
ED is a symptom, not a disease. Some patients may not be properly evaluated or receive treatment for	4
an underlying disease or condition that may be causing ED.	
ED is common after RP, irrespective of the surgical technique used.	2b
ED is common after external radiotherapy and brachytherapy.	2b
ED is common after cryotherapy and high-intensity focused US.	2b

3.1.2 Classification

Erectile Dysfunction is commonly classified into three categories based on its aetiology. These include organic, psychogenic and mixed ED. However, this classification should be used with caution since most cases are actually of mixed aetiology. It is therefore suggested to use the term primary organic or primary psychogenic.

3.1.3 Diagnostic evaluation

3.1.3.1 Basic work-up

The first step in evaluating ED is always a detailed medical and sexual history of patients and, when available, their partners [62]. In this context, taking a comprehensive medical history may reveal one of the many common disorders associated with ED [62]. It is important to establish a relaxed atmosphere during history-taking. This will make it easier to i) ask questions about erectile function and other aspects of the sexual history; and, ii) to explain the diagnosis and therapeutic approach to the patient and his partner. Figure 1 lists the minimal diagnostic evaluation (basic work-up) in patients with ED.

3.1.3.1.1 Sexual history

The sexual history must include information about sexual orientation, previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. The sexual health status of the partner(s) (when available) can also be useful.

A detailed description should be made of the rigidity and duration of both sexually-stimulated and morning erections and of problems with sexual desire, arousal, ejaculation, and orgasm [63, 64]. Validated psychometric questionnaires, such as the International Index for Erectile Function (IIEF) [65] or its short version the Sexual Health Inventory for Men (SHIM) [66], help to assess the different sexual function domains (i.e. sexual desire, erectile function, orgasmic function, intercourse, and overall satisfaction), as well as the potential impact of a specific treatment modality.

Psychometric analyses also support the use of the erectile hardness score for the assessment of penile rigidity in practice and in clinical trials research [67]. In cases of clinical depression, the use of a 2-question scale for depression is recommended in everyday clinical practice: "During the past month have you often been bothered by feeling down, depressed or hopeless? During the past month have you often been bothered by little interest or pleasure, doing things?" [68]. Patients should always be screened for symptoms of possible hypogonadism (= testosterone deficiency), including decreased energy, libido, fatigue and cognitive impairment, as well as for LUTS. In this regard, although LUTS/BPH in itself does not represent a contraindication to treat a patient for late onset hypogonadism, screening for LUTS severity is clinically relevant [69].

3.1.3.1.2 Physical examination

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular and neurological systems [70, 71]. A physical examination may reveal unsuspected diagnoses, such as Peyronie's disease, pre-malignant or malignant genital lesions, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggesting hypogonadism (small testes, alterations in secondary sexual characteristics etc.). Blood pressure and heart rate should be measured if they have not been assessed in the previous three to six months. Likewise either BMI calculation or waist circumference measurement should be taken into consideration in every patient with comorbid conditions.

3.1.3.1.3 Laboratory testing

Laboratory testing must be tailored to the patient's complaints and risk factors. Patients may need a fasting blood glucose or HbA1c and lipid profile if they have not recently been assessed. Hormonal tests include an early morning total testosterone. If indicated, the bio-available or calculated-free testosterone may be needed to corroborate total testosterone measurements. However, the threshold of testosterone required to maintain an erection is low and ED is usually a symptom of more severe cases of hypogonadism [35, 72-74]. For levels > 8 nmol/l the relationship between circulating testosterone and sexual functioning is very low [35, 72-74]. Additional laboratory tests may be considered in selected patients (e.g., prostate-specific antigen (PSA) [75]; prolactin, and luteinising hormone [76]. Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, these present opportunities to identify critical comorbid conditions that should not be missed [71].

Figure 1: Minimal diagnostic evaluation (basic work-up) in patients with ED

ED = erectile dysfunction; IIEF = International Index of Erectile Function.

3.1.3.1.4 Cardiovascular system and sexual activity: the patient at risk

Patients who seek treatment for sexual dysfunction have a high prevalence of CVDs. Epidemiological surveys have emphasised the association between cardiovascular and metabolic risk factors and sexual dysfunction in both men [77] and women [78]. Overall, ED can improve the sensitivity of screening for asymptomatic CVD in men with diabetes [79, 80]. ED significantly increases the risk of CVD, coronary heart disease, stroke, and all these cause mortality, and the increase is probably independent of conventional cardiovascular risk factors [28, 29, 81]. Longitudinal data from an observational population-based study of 965 men without CVD, showed that younger men (< 50 years) with persistent ED have an increased Framingham risk that is independent of traditional CVD risk factors [82].

The EAU Guidelines for diagnosing and treating men with ED have been adapted from previously published recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk [83]. The Princeton Consensus (Expert Panel) Conference is dedicated to optimising sexual function and preserving cardiovascular health [83-85]. Accordingly, patients with ED can be stratified into three cardiovascular risk categories (Table 2), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 2). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, which can be determined when taking the patient's history [40].

Table 2: Cardiac risk stratification (based on 2nd and 3rd Princeton Consensus [83, 85])

Low-risk category	Intermediate-risk category	High-risk category
Asymptomatic, < 3 risk factors for	\geq 3 risk factors for CAD	High-risk arrhythmias
CAD (excluding sex)	(excluding sex)	
Mild, stable angina	Moderate, stable angina	Unstable or refractory angina
(evaluated and/or being treated)		
Uncomplicated previous MI	Recent MI (> 2, < 6 weeks)	Recent MI (< 2 weeks)
LVD/CHF (NYHA class I or II)	LVD/CHF (NYHA class III)	LVD/CHF (NYHA class IV)
Post-successful coronary	Non-cardiac sequelae of	Hypertrophic obstructive and other
revascularisation	atherosclerotic disease (e.g.,	cardiomyopathies
	stroke, peripheral vascular disease)	
Controlled hypertension		Uncontrolled hypertension
Mild valvular disease		Moderate-to-severe valvular
		disease

CAD = coronary artery disease; CHF = congestive heart failure; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Figure 2: Treatment algorithm for determining level of sexual activity according to cardiac risk in Erectile Dysfunction (based on 3rd Princeton Consensus) [83]

^a Sexual activity is equivalent to walking 1 mile on the flat in 20 minutes or briskly climbing two flights of stairs in 10 seconds.

^b Sexual activity is equivalent to four minutes of the Bruce treadmill protocol.

3.1.3.1.4.1 Low-risk category

The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low-risk is typically implied by the ability to perform exercise of modest intensity, which is defined as, \ge 6 metabolic equivalents of energy expenditure in the resting state without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before the initiation or resumption of sexual activity or therapy for sexual dysfunction.

3.1.3.1.4.2 Intermediate- or indeterminate-risk category

The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

3.1.3.1.4.3 High-risk category

High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderate-to-severe symptomatic heart disease. High-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient's cardiac condition has been stabilised by treatment, or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

3.1.3.2 Specialised diagnostic tests

Most patients with ED can be managed within the sexual care setting; conversely, some patients may need specific diagnostic tests (Tables 3 and 4).

3.1.3.2.1 Nocturnal penile tumescence and rigidity test

The nocturnal penile tumescence and rigidity assessment should be performed on at least two separate nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for ten or more minutes [86].

3.1.3.2.2 Intracavernous injection test

The intracavernous injection test gives limited information about the vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within ten minutes after the intracavernous injection and lasts for 30 minutes [87]. Overall, the test is inconclusive as a diagnostic procedure and a duplex Doppler study of the penis should be requested, if clinically warranted.

3.1.3.2.3 Duplex ultrasound of the penis

A peak systolic blood flow > 30 cm/s, an end-diastolic velocity of < 3 cm/s and a resistance index > 0.8 are generally considered normal [88]. Further vascular investigation is unnecessary when a duplex ultrasound (US) examination is normal.

3.1.3.2.4 Arteriography and dynamic infusion cavernosometry or cavernosography

Arteriography and dynamic infusion cavernosometry or cavernosography should be performed only in patients who are being considered for vascular reconstructive surgery [89].

3.1.3.2.5 Psychiatric assessment

Whenever clinically indicated, patients with psychiatric disorders should be referred to a psychiatrist who is particularly interested in sexual health. In younger patients (< 40 years) with long-term primary ED [34], psychiatric assessment may be helpful before any organic assessment is carried out.

3.1.3.2.6 Penile abnormalities

Surgical correction may be needed in patients with ED and penile abnormalities (e.g. hypospadias, congenital curvature, or Peyronie's disease with preserved rigidity).

3.1.3.3 Patient education - consultation and referrals

Consultation with the patient should include a discussion of the expectations and needs of both the patient and their sexual partner. It should also review both the patient's and partner's understanding of ED and the results of diagnostic tests, and provide a rational selection of treatment options [90]. Patient and partner education is an essential part of ED management [90, 91].

Table 3: Indications for specific diagnostic tests

Primary ED (not caused by organic disease or psychogenic disorder).

Young patients with a history of pelvic or perineal trauma, who could benefit from potentially curative revascularisation surgery or angioplasty.

Patients with penile deformities which might require surgical correction (e.g., Peyronie's disease, congenital penile curvature).

Patients with complex psychiatric or psychosexual disorders.

Patients with complex endocrine disorders.

Specific tests may be indicated at the request of the patient or his partner.

Medico-legal reasons (e.g., implantation of penile prosthesis to document end stage ED, sexual abuse).

Table 4: Specific diagnostic tests

Nocturnal Penile Tumescence and Rigidity (NTPR) using Rigiscan®
Vascular studies
- Intracavernous vasoactive drug injection
- Penile Dynamic Duplex Ultrasonography
- Penile Dynamic Infusion Cavernosometry and Cavernosography
- Internal pudendal arteriography
Neurological studies (e.g., bulbocavernosus reflex latency, nerve conduction studies)
Endocrinological studies
Specialised psychodiagnostic evaluation

3.1.3.4 Recommendations for the diagnostic evaluation of ED

Recommendations	LE	GR
Take a comprehensive medical and sexual history in every patient.	3	В
Use a validated questionnaire related to erectile dysfunction to assess all sexual function	3	В
domains and the effect of a specific treatment modality.		
Include a physical examination in the initial assessment of men with erectile dysfunction (ED) to	4	В
identify underlying medical conditions that may be associated with ED.		
Assess routine laboratory tests, including glucose-lipid profile and total testosterone, to identify	4	В
and treat any reversible risk factors and lifestyle factors that can be modified.		
Include specific diagnostic tests in the initial evaluation only in the presence of the conditions	4	В
presented in Table 3.		

3.1.4 **Disease management**

3.1.4.1 Treatment options

Erectile dysfunction may be associated with modifiable or reversible risk factors, including lifestyle or drugrelated factors [30]. These factors may be modified either before, or at the same time as, specific therapies are used. Likewise, ED may be associated with concomitant and underlying conditions (such as, endocrine disorders and metabolic disorders - e.g. diabetes - some cardiovascular problems - e.g. hypertension) which should always be well-controlled as the first step of ED treatment [92]. As a rule, ED can be treated successfully with current treatment options, but it cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g. hypogonadism and hyperprolactinaemia) [73, 76], which potentially can be cured with specific treatment. Most men with ED will be treated with therapeutic options that are not cause specific. This results in a structured treatment strategy that depends on efficacy, safety, invasiveness and cost, as well as patient preference [90]. In this context, physician-patient (partner) dialogue is essential throughout the management of ED. The assessment of treatment options must be tailored according to patient and partner satisfaction, QoL factors as well as treatment-related safety and efficacy. A treatment algorithm for ED is shown in Figure 3.

3.1.4.1.1 Lifestyle management of ED with concomitant risk factors

The basic work-up of the patient must identify reversible risk factors for ED. Lifestyle changes and risk factor modification must precede or accompany any pharmacological treatment. Major clinical potential benefits of lifestyle changes may be obtained in men with specific comorbid cardiovascular or metabolic disorders, such as diabetes or hypertension [30, 93].

3.1.4.1.2 Erectile dysfunction after radical prostatectomy

Use of pro-erectile drugs following RP is important in achieving post-operative erectile function. Several trials have shown higher rates of erectile function recovery after RP in patients receiving any drug (therapeutic or prophylactic) for ED. Early compared with delayed erectile function treatment seems to impact on the natural healing time of potency [48]. Currently available therapeutic armamentarium follows the treatment algorithm for ED which is shown in Figure 3.

The management of post-RP ED has been revolutionised by the advent of phosphodiesterase 5 inhibitors (PDE5Is), with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. It must be emphasised that post-RP, ED patients are poor responders to PDE5Is. However, PDE5Is are considered as the first-line therapy in patients who have undergone nerve-sparing (NS) surgery regardless of the surgical technique used [48, 49]. A number of clinical parameters have been identified as potential predictors of PDE5Is in men undergoing RP. Patient age and quality of NS technique are key factors in preserving post-RP erectile function [48, 49, 52]. The response rate to sildenafil treatment for ED after RP in different trials has ranged from 35% to 75% among those who underwent NSRP and from 0% to 15% among those who underwent non-NSRP [48, 94]. Early use of high-dose sildenafil after RP has been suggested to be associated with preservation of smooth muscle within the corpora cavernosa [95]. Daily sildenafil also results in a greater return of spontaneous normal erectile function after RP compared to placebo following bilateral NSRP in patients who were fully potent before surgery [96]. Conversely, a recent prospective, randomised, placebo-controlled study, which assessed the effects of nightly sildenafil citrate therapy during penile rehabilitation using nocturnal penile rigidity in addition to the IIEF-EF, showed no therapeutic benefit for nightly sildenafil when compared to on-demand dosing in determining recovery of erectile function post-prostatectomy [97].

The effectiveness of tadalafil and vardenafil as on-demand treatment has been evaluated in post-RP ED. A large multicentre trial in Europe and the USA has studied tadalafil in patients with ED following bilateral NS surgery. Erectile function was improved in 71% of patients treated with 20 mg tadalafil vs. 24% of those treated with placebo, while the rate of successful intercourse attempts was 52% with 20 mg tadalafil vs. 26% with placebo [98]. Similarly, vardenafil has been tested in patients with ED following NSRP in a randomised, multicentre, prospective, placebo-controlled study in North America [99]. Following bilateral NSRP, erectile function improved by 71% and 60% with 10 and 20 mg vardenafil, respectively. An extended analysis of the same cohort of patients showed the benefit of vardenafil compared to placebo in terms of intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience [100]. Moreover, a randomised, double-blind, double-dummy trial in men < 68 years of age and normal pre-operative erectile function who underwent NSRP at 50 centres from nine European countries and Canada, compared tadalafil once daily with placebo [101]. Tadalafil was most effective for drug-assisted erectile function in men with ED following NSRP, and data suggested a potential role for tadalafil once daily - provided early after surgery - in contributing to the recovery of post-operative erectile function and possibly protecting penile structural changes [101]. Unassisted erectile function was not improved after cessation of active therapy for nine months [101]. Moreover, taking tadalafil once daily significantly shortened time to erectile function recovery versus placebo over the nine month double/blind treatment period. Conversely tadalafil on demand did not [102]. Likewise, tadalafil once daily improved QoL post-operatively, both at double-blind treatment and open label treatment period [103].

A randomised, double-blind, double-dummy, multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP [104]. In patients whose pre-operative erectile function domain score was > 26, vardenafil was efficacious when used on demand, supporting a paradigm shift towards on-demand dosing with PDE5Is in post-RP ED [104]. A double-blind, placebo-controlled, parallel-group, study in 298 patients with ED after bilateral NSRP randomised to 100 or 200 mg avanafil or placebo (taken 30 minutes before sexual activity) for twelve weeks showed significantly greater increases in sexual encounter profile (SEP) question 2 and SEP3 as well as in mean change of IIEF erectile function domain score with 100 and 200 mg avanafil vs. placebo (p < 0.01) [85].

For dosing with avanafil 36.4% (28 of 77) of sexual attempts (SEP3) at fifteen minutes or less were successful vs. 4.5% (2 of 44) for placebo (p < 0.01) [105]. A recently conducted meta-analysis confirmed that avanafil had comparable efficacy with sildenafil, vardenafil and tadalafil treatments [106]. Although some authors reported improved erectile function when long-term tadalafil 5 mg once daily is combined with sildenafil as needed [107], more safety analyses are required to recommend such a therapy.

Historically, the treatment options for post-RP ED have included intracavernous injections [108], urethral microsuppository [48, 109], vacuum device therapy [48, 110], and penile implants [48, 111, 112].

Intracavernous injections and penile implants are still suggested as second- and third-line treatments, respectively, when oral PDE5Is are not adequately effective or contraindicated for post-operative patients (Sections 3.1.4.3 and 3.1.4.4). Recently, the data from a human phase 1 trial with a single intracavernosal injection of autologous adipose-derived regenerative cells (ADRCs) freshly isolated after a liposuction in post-prostatectomy ED patients, showed promising results in restoring normal erectile function with only minor side-effects [113].

Figure 3: Treatment algorithm for erectile dysfunction

3.1.4.1.3 Causes of ED that can be potentially treated with a curative intent

3.1.4.1.3.1 Hormonal causes

The advice of an endocrinologist may be beneficial for managing patients with hormonal abnormalities [76]. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes (e.g. a functional pituitary tumour resulting in hyperprolactinaemia) [76, 114]. When clinically indicated [115], testosterone supplementation (TS) (intramuscular, oral, or transdermal) is effective, but should only be used after other endocrinological causes for testicular failure have been excluded [35, 73, 116]. Before initiating TS, digital rectal examination (DRE), serum PSA test, haematocrit, liver function tests and lipid profile should be performed [35, 73, 117]. Patients who are given TS should be monitored for clinical response, elevation of haematocrit and development of hepatic or prostatic disorders [35, 73, 117]. Testosterone supplementation is controversial in men with a history of PCa (LE: 4) [118]. Since there is limited evidence suggesting that TS may not pose an undue risk of PCa recurrence or progression, TS is contraindicated in patients with untreated PCa (LE: 4).

Testosterone supplementation is contraindicated in patients with unstable cardiac disease [69, 119]. Conversely, the role of testosterone in the cardiovascular health of men is controversial. Clinical trials examining TS have been insufficiently powered to provide definitive and unequivocal evidence of adverse events in terms of cardiovascular outcomes [120-125]. Current guidelines from the Endocrine Society make no recommendations on whether patients with heart disease should be screened for hypogonadism and do not recommend supplementing testosterone in patients with heart disease to improve survival [72]. However, a recent comprehensive SR and meta-analysis of all placebo-controlled RCTs on the effect of TS on cardiovascular-related problems did not support a causal role between TS and adverse cardiovascular events [119].

3.1.4.1.3.2 Post-traumatic arteriogenic ED in young patients

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% longterm success rate [126]. The lesion must be confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by dynamic infusion cavernosometry or cavernosography. Vascular surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results [126].

3.1.4.1.3.3 Psychosexual counselling and therapy

For patients with a significant psychological problem, psychosexual therapy may be given either alone or with another therapeutic approach in order to improve couple sexual satisfaction and female sexual function [127]. Psychosexual therapy requires ongoing follow-up and has had variable results [128].

3.1.4.2 First-line therapy

3.1.4.2.1 Oral pharmacotherapy

Phosphodiesterase 5 inhibitor hydrolyses cyclic guanosine monophosphate (cGMP) in the cavernosal tissue. Inhibition of PDE5 results in smooth muscle relaxation with increased arterial blood flow, leading to compression of the subtunical venous plexus followed by penile erection [129]. Four potent selective PDE5Is have been approved by the European Medicines Agency (EMA) for the treatment of ED [130]. They are not initiators of erection and require sexual stimulation to facilitate an erection. Efficacy is defined as an erection with rigidity sufficient for penetration.

Sildenafil

Sildenafil was launched in 1998 and was the first PDE5I available on the market [131]. It is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient's response and side-effects [131]. Sildenafil is effective from 30-60 minutes after administration [131]. Its efficacy is reduced after a heavy, fatty meal due to delayed absorption. Efficacy may be maintained for up to twelve hours [132]. The pharmacokinetic data of sildenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use [133, 134]. After 24 weeks in a dose-response study, improved erections were reported by 56%, 77% and 84% of a general ED population taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo [135]. Sildenafil significantly improved patient scores for IIEF, SEP2, SEP3, and General Assessment Questionnaire (GAQ) and treatment satisfaction. The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established. (LE: 1). Recently, an orally disintegrating tablet (ODT) of sildenafil citrate at the dosage of 50 mg has been developed mainly for the benefit of patients who have difficulty swallowing solid dosage forms.

Tadalafil

Tadalafil was licensed for treatment of ED in February 2003 and is effective from 30 minutes after administration, with peak efficacy after about two hours [136]. Efficacy is maintained for up to 36 hours [136] and is not affected by food. It is administered in on-demand doses of 10 and 20 mg and also an alternative daily dose of 5 mg. The recommended on-demand starting dose is 10 mg and should be adapted according to the patient's response and side-effects [136, 137]. Pharmacokinetic data of tadalafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use. In premarketing studies, after twelve weeks of treatment and in a dose-response study, improved erections were reported by 67% and 81% of a general ED population taking 10 and 20 mg tadalafil, respectively, compared to 35% of men in the control placebo group [136]. Tadalafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction [136].

Efficacy has been confirmed in post-marketing studies [130, 138]. The efficacy of tadalafil in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g. diabetes mellitus), has been successfully established [139]. Daily tadalafil has also been licensed for the treatment of LUTS secondary to BPH. Therefore, it is useful in patients with concomitant ED and LUTS [140].

Vardenafil

Vardenafil became commercially available in March 2003 and is effective from 30 minutes after administration [139]. Its effect is reduced by a heavy, fatty meal (> 57% fat). 5, 10 and 20 mg doses have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient's response and side-effects [141]. Pharmacokinetic data of vardenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use [141]. After twelve weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of a general ED population taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo [141, 142]. Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. Efficacy has been confirmed in post-marketing studies [141, 142]. The efficacy of vardenafil in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g. diabetes mellitus), has been successfully established. More recently, an ODT form of vardenafil has been released [142]. Orodispersable tablet formulations offer improved convenience over film-coated formulations and may be preferred by patients. Absorption is unrelated to food intake and they exhibit better bio-availability compared to film-coated tablets [143]. The efficacy of vardenafil ODT has been demonstrated in several RCTs and did not seem to differ from the regular formulation [143-145].

Avanafil

Avanafil is a highly-selective PDE5I that became commercially available in 2013 [146]. Avanafil has a high ratio of inhibiting PDE5 as compared with other PDE subtypes allowing for the drug to be used for ED while minimising adverse effects [147]. 50 mg, 100 mg, and 200 mg doses have been approved for on-demand treatment of ED [146]. The recommended starting dose is 100 mg taken as needed approximately 15 to 30 minutes before sexual activity and the dosage may be adapted according to efficacy and tolerability [146, 148, 149]. In the general population with ED, the mean percentage of attempts resulting in successful intercourse was approximately 47%, 58%, and 59% for the 50 mg, 100 mg, and 200 mg avanafil groups, respectively, as compared with approximately 28% for placebo [146, 148]. Data from sexual attempts made within fifteen minutes of dosing showed successful attempts in 64%, 67%, and 71% of cases, with avanafil 50, 100, and 200 mg, respectively. The maximum recommended dosing frequency is once per day. Dosage adjustments are not warranted based on renal function, hepatic function, age or gender [148]. Pharmacokinetic data of avanafil are presented in Table 5 [146, 148]. Adverse events are generally mild in nature (Table 6) [146, 148]. Pairwise metaanalytic data from available studies suggested that avanafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ, with an evident dose-response relationship [146, 150]. Administration with food may delay the onset of effect compared with administration in the fasting state but avanafil can be taken with or without food. The efficacy of avanafil in many groups of patients with ED, including difficult-to-treat subgroups (e.g diabetes mellitus), has been successfully established.

Choice or preference between the different PDE5Is

To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for sildenafil, tadalafil, vardenafil, and avanafil. Choice of drug will depend on the frequency of intercourse (occasional use or regular therapy, three to four times weekly) and the patient's personal experience. Patients need to know whether a drug is short- or long-acting, its possible disadvantages, and how to use it. A recent meta-analysis demonstrated that ED patients who prioritise high efficacy must use sildenafil 50 mg whereas those who optimise tolerability should initiate with tadalafil 10 mg treatment and switch to udenafil 100 mg if the treatment is not sufficient [138]. Of clinical relevance, udenafil is not an EMEA or FDA

approved drug. Results of another clinical trial revealed that tadalafil 5 mg once daily may improve the erectile function outcomes among men who had a partial response to on-demand PED5I therapy [151].

Continuous use of PDE5Is

Animal studies have shown that chronic use of PDE5 inhibitors significantly improves or prevents the intracavernous structure alterations due to age, diabetes, or surgical damage [152-156]. No data exists for a human population. In humans, it has been clinically demonstrated that treatment with tadalafil 5 mg once daily in men complaining of ED of various severities was well tolerated and effective [157]. In 2007, tadalafil 2.5 and 5 mg were approved by the EMA for daily treatment of ED. According to EMA, a once daily regimen with tadalafil 2.5 mg or 5 mg might be considered suitable, based on patient choice and the physician's judgement. In these patients, the recommended dose is 5 mg, taken once a day at approximately the same time. Overall, tadalafil, 5 mg once daily, provides an alternative to on-demand dosing of tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be temporally linked. The appropriateness of the continuous use of a daily regimen should be re-assessed periodically [157, 158]. Continuous dosing may also be used in the comorbid patient with LUTS and ED.

Table 5: Summary of the key pharmacokinetic data for the four PDE5Is currently EMA-approved to treat	at
ED*	

Parameter	Sildenafil, 100 mg	Tadalafil, 20 mg	Vardenafil, 20 mg	Avanafil 200mg
C _{max}	560 μg/L	378 µg/L	18.7 µg/L	5.2 μg/L
T _{max} (median)	0.8-1 hours	2 hours	0.9 hours	0.5-0.75 hours
T1/2	2.6-3.7 hours	17.5 hours	3.9 hours	6-17 hours
AUC	1,685 µg.h/L	8,066 µg.h/L	56.8 µg.h/L	11.6 µg.h/L
Protein binding	96%	94%	94%	99%
Bioavailability	41%	NA	15%	8-10%

* Fasted state, higher recommended dose. Data adapted from EMA statements on product characteristics. *C_{max}*: maximal concentration, *T_{max}*: time-to-maximum plasma concentration; T1/2: plasma elimination halftime; AUC: area under curve or serum concentration time curve.

Adverse event	Sildenafil	Tadalafil	Vardenafil	Avanafil 200mg
Headache	12.8%	14.5%	16%	9.3%
Flushing	10.4%	4.1%	12%	3.7%
Dyspepsia	4.6%	12.3%	4%	uncommon
Nasal congestion	1.1%	4.3%	10%	1.9%
Dizziness	1.2%	2.3%	2%	0.6%
Abnormal vision	1.9%		< 2%	none
Back pain		6.5%		< 2%
Myalgia		5.7%		< 2%

Table 6: Common adverse events of the four PDE5Is currently EMA-approved to treat ED*

* Adapted from EMA statements on product characteristics.

Safety issues for PDE5Is

(i) Cardiovascular safety

Clinical trial results for the four PDE5Is and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5Is, as part of either RCTs or open-label studies, or compared to expected rates in age-matched male populations. None of the PDE5Is had an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina. Chronic or on-demand use is well tolerated with a similar safety profile. All PDE5Is are contraindicated in: i) patients who have suffered from a myocardial infarction, stroke, or life-threatening arrhythmia within the last six months; ii) patients with resting hypotension (blood pressure < 90/50 mmHg) or hypertension (blood pressure > 170/100 mmHg); iii) patients with unstable angina, angina with sexual intercourse, or congestive heart failure categorised as New York Heart Association Class IV [83, 159-161].

(ii) Nitrates are contraindicated with PDE5Is

Absolute contraindication to PDE5Is is represented by patients who are using any form of organic nitrate (e.g.nitroglycerine, isosorbide mononitrate, and isosorbide dinitrate) or nitric oxide (NO) donors (e.g. other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate such as "poppers" which is used for recreation). They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5Is depends upon the PDE5I and nitrate used. If a PDE5I is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 hours if sildenafil (and probably also vardenafil) is used (half-life, four hours), or at least 48 hours if tadalafil is used (half-life, 17.5 hours), and for no less than twelve hours if avanafil is used (half-life, 6-17 hours) [162].

(iii) Antihypertensive drugs

Co-administration of PDE5Is with antihypertensive agents (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, β -blockers, and diuretics) may result in small additive decreases in blood pressure, which are usually minor [83]. In general, the adverse event profile of a PDE5I is not worsened by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents [163].

α -Blocker interactions

All PDE5Is show some interaction with α -blockers, which under some conditions may result in orthostatic hypotension.

- Sildenafil labelling advises that 50 or 100 mg sildenafil should be used with caution in patients taking an α-blocker (especially doxazosin). Hypotension is more likely to occur within four hours following treatment with an α-blocker. A starting dose of 25 mg is recommended [133].
- Concomitant treatment with vardenafil should only be initiated if the patient has been stabilised on his α-blocker therapy. Co-administration of vardenafil with tamsulosin is not associated with clinically significant hypotension [139, 141, 142].
- Tadalafil is not recommended in patients taking doxazosin, but this is not the case for tamsulosin [136, 164].
- Avanafil labelling currently reports that patients should be stable on α-blocker therapy prior to initiating avanafil. In these patients, avanafil should be initiated at the lowest dose of 50 mg. Conversely, in those patients already taking an optimised dose of avanafil, α-blocker therapy should be initiated at the lowest dose.

Dosage adjustment

Drugs that inhibit the CYP34A pathway will inhibit the metabolic breakdown of PDE5Is, thus increasing PDE5Is blood levels (e.g. ketoconazole, ritonavir, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, saquinavir and telithromycin). Therefore, lower doses of PDE5Is are necessary. However, other agents, such as rifampin, phenobarbital, phenytoin and carbamazepine, may induce CYP3A4 and enhance the breakdown of PDE5Is, so that higher doses of PDE5Is are required. Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

Management of non-responders to PDE5Is

The two main reasons why patients fail to respond to a PDE5I are either incorrect drug use or lack of efficacy of the drug. Data suggest that an adequate trial involves at least six attempts with a particular drug [165]. The management of non-responders depends upon identifying the underlying cause. Check that the patient has been using a licensed medication. There is a large counterfeit market in PDE5Is. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

Check that the medication has been properly prescribed and correctly used. The main reason why patients fail to use their medication correctly is inadequate counselling from their physician. The most common causes of incorrect drug use are: i) failure to use adequate sexual stimulation; ii) failure to use an adequate dose; and, iii) failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

PDE5I action is dependent on the release of NO by the parasympathetic nerve endings in the erectile tissue of the penis. The usual stimulus for NO release is sexual stimulation, and without adequate sexual stimulation (and NO release), the medication is ineffective. Oral PDE5Is take different times to reach maximal plasma concentrations [132, 134, 143, 150, 166-168]. Although pharmacological activity is achieved at plasma levels well below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all four drugs have an onset of

action in some patients within 15-30 minutes of oral ingestion [134, 143, 150, 166-168], most patients require a longer delay between taking the medication [141, 150, 169, 170]. Absorption of sildenafil can be delayed by a meal, and absorption of vardenafil can be delayed by a fatty meal [171]. Absorption of tadalafil is less affected provided there is enough delay between oral ingestion and an attempt at sexual intercourse [166]. When avanafil is taken with a high fat meal, the rate of absorption is reduced with a mean delay in T_{max} of 1.25 hours and a mean reduction in C_{max} of 39% (200 mg). There is no effect on the extent of exposure (AUC). The small changes in avanafil C_{max} are considered to be of minimal clinical significance [146, 147, 150].

It is possible to wait too long after taking the medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is about four hours, suggesting that the normal window of efficacy is six to eight hours following drug ingestion, although responses following this time period are well recognised. The half-life of avanafil is six to seventeen hours. Tadalafil has a longer half-life of ~17.5 hours, so the window of efficacy is much longer at ~36 hours. Data from uncontrolled studies suggest patient education can help salvage an apparent non-responder to a PDE5I [172-176]. After emphasising the importance of dose, timing, and sexual stimulation to the patient, erectile function can be effectively restored following re-administration of the relevant PDE5I [172-174].

Very recently, data suggested that response to sildenafil treatment was also dependent on polymorphism in the PDE5A gene, which encodes the principal cGMP-catalyzing enzyme in the penis, regulating cGMP clearance, and it is the primary target of sildenafil [177]. Overall, the findings of a meta-regression aimed at evaluating the effectiveness and prognostic factors of PDE5I to treat ED showed that PDE5Is are more effective in Caucasians than Asians, and in patients with more severe ED [178].

Clinical strategies in patients correctly using a PDE5Is

There is controversial evidence suggesting that, in patients with testosterone deficiency, TS might improve a patient's response to a PDE5I [73, 179-181]. Modification of other risk factors may also be beneficial as discussed in section 3.1.4.1.1. Limited data suggest that some patients might respond better to one PDE5I than to another [182]. Although these differences might be explained by variations in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5I might be helpful. Moreover, mainly in patients with severe ED, it has been suggested to combine tadalafil daily dosing with short acting PDE5I (such as sildenafil), without any significant increase in terms of side-effects [183]. If drug treatment fails, then patients should be offered an alternative therapy such as intracavernous injection therapy or use of a vacuum erection device (VED).

The combination of long-acting injectable testosterone undecanoate and tadalafil 5 mg once daily produced a significant improvement in terms of EF of combined treatment [184]. Moreover, the improvement in EF was well maintained, even after the cessation of treatment.

3.1.4.2.2 Vacuum erection devices

Vacuum erection devices (VED) provide passive engorgement of the corpora cavernosa, together with a constrictor ring placed at the base of the penis to retain blood within the corpora. Published data report that efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% [185, 186]. Most men who discontinue use of VEDs do so within three months. Long-term use of VEDs decreases to 50-64% after two years [187]. The most common adverse events include pain, inability to ejaculate, petechiae, bruising, and numbness, which occur in < 30% of patients [186]. Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 minutes after intercourse. Vacuum erection devices are contraindicated in patients with bleeding disorders or on anticoagulant therapy. Vacuum erection devices may be the treatment of choice in well-informed older patients with infrequent sexual intercourse and comorbidity requiring non-invasive, drug-free management of ED [185, 186].

3.1.4.2.3 Shockwave therapy

The use of low-intensity extracorporeal shockwave therapy (LI-SWT) was proposed as a novel treatment for ED [188-192]. In this context, the number of studies of LI-SWT for ED has increased dramatically throughout recent years. Overall, most of these studies reported encouraging results, regardless of variation in LI-SWT set-up parameters or treatment protocols. As a whole these studies suggest that LI-SWT could significantly improve the IIEF and Erection Hardness Score of ED patients [193]. The publication of robust evidence from additional RCTs and longer-term follow-up would provide more confidence regarding use of LI-SWT for ED patients. Therefore clear recommendations cannot be given.

3.1.4.3 Second-line therapy

Patients not responding to oral drugs may be offered intracavernous injections. The success rate is high (85%) [194, 195]. Intracavernous administration of vasoactive drugs was the first medical treatment for ED introduced more than twenty years ago [176, 196].

3.1.4.3.1 Intracavernous injections

3.1.4.3.1.1 Alprostadil

Alprostadil (CaverjectTM, Edex/ViridalTM) was the first and only drug approved for intracavernous treatment of ED [176, 196]. Intracavernous alprostadil is most efficacious as monotherapy at a dose of 5-40 µg (of note, 40 µg dose is not registered in every European country). The erection appears after five to fifteen minutes and lasts according to the dose injected. An office-training programme is required for the patient to learn the correct injection process. In cases of limited manual dexterity, the technique may be taught to their partners. The use of an automatic special pen that avoids a view of the needle can resolve fear of penile puncture and simplifies the technique. Efficacy rates for intracavernous alprostadil of > 70% have been found in the general ED populations, as well as in patient subgroups (e.g. diabetes or CVD), with reported sexual activity of 94% after the injections and satisfaction rates of 87-93.5% in patients and 86-90.3% in partners [176, 196]. Complications of intracavernous alprostadil include penile pain (50% of patients reported pain only after 11% of total injections), prolonged erections (5%), priapism (1%), and fibrosis (2%) [176, 196, 197]. Pain is usually self-limited after prolonged use. It can be alleviated with the addition of sodium bicarbonate or local anaesthesia [176, 196, 198]. Cavernosal fibrosis (from a small haematoma) usually clears within a few months after temporary discontinuation of the injection programme. However, tunical fibrosis suggests early onset of Peyronie's disease and may indicate stopping intracavernous injections indefinitely. Systemic side-effects are uncommon. The most common is mild hypotension, especially when using higher doses. Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders. Despite these favourable data, drop-out rates of 41-68% have been described for intracavernous pharmacotherapy [176, 196, 199, 200], with most drop-outs occurring within the first two to three months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rate (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year. Reasons for discontinuation included desire for a permanent modality of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop-out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up is important in addressing patient withdrawal from an intracavernous injection programme [201].

3.1.4.3.1.2 Combination therapy

Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating side-effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly
 used in combination therapy due to its high incidence of side-effects as monotherapy. Papaverine is
 currently not licensed for the treatment of ED.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide, usually combined with the main drugs [202, 203]. Most combinations are not standardised and some drugs have limited availability worldwide.
- Papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 µg), have been widely used with improved efficacy rates, although they have never been licensed for ED [204, 205]. The triple combination regimen of papaverine, phentolamine and alprostadil has the highest efficacy rates, reaching 92%; this combination has similar side-effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on total dose).
- Vasoactive intestinal peptide (VIP) (25 µg) plus phentolamine mesylate (1-2 mg) (Invicorp[™], currently licensed in Scandinavia), is a combination of two active components with complementary modes of action. Clinical studies showed that the combination is an effective treatment for intracavernous injections in > 80% of men with ED, including those who have failed to respond to other therapies and, unlike existing intracavernous therapies, is associated with a very low incidence of penile pain and virtually negligible risk of priapism [206].

Despite high efficacy rates, 5-10% of patients do not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone [207]. However, combination therapy is associated with an increased incidence of adverse effects in 33% of patients, including dizziness in 20% of patients. This strategy can be considered in carefully selected patients before proceeding to a penile implant (LE: 4).

3.1.4.3.1.3 Intraurethral/topical alprostadil

A specific formulation of alprostadil (125-1000 μ g) in a medicated pellet (MUSETM) has been approved as a treatment for ED [208]. Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, only the higher doses (500 and 1,000 μ g) have been used with low consistency response rates [208-210]. The application of a constriction ring at the root of the penis (ACTISTM) may improve efficacy [209, 210].

The most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are very rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration. Efficacy rates are significantly lower than intracavernous pharmacotherapy [195]. Intraurethral pharmacotherapy is a second-line therapy and provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less-efficacious treatment.

Topical alprostadil is another way of administering alprostadil. It is a cream that includes a permeation enhancer in order to facilitate absorption of alprostadil (200 and 300µg) through the urethral meatus [211]. Clinical data are limited. Significant improvement compared to placebo was recorded for IIEF, SEP2 and SEP3 in a broad range of patients with mild-to-severe ED [212]. Side-effects include penile erythema, penile burning and pain. Systemic side-effects are very rare. Topical alprostadil is approved and it is only available in some European countries.

3.1.4.4 Third-line therapy (penile prostheses)

The surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution to their problem [213]. The two currently available classes of penile implants include inflatable (2- and 3-piece) and malleable devices [48, 111, 214, 215]. Most patients prefer the 3-piece inflatable devices due to the more "natural" erections obtained. Likewise, 3-piece inflatable devices provide the best rigidity and the best flaccidity because they will fill every part of the corporal bodies. However, the 2-piece inflatable prosthesis can be a viable option among patients who are deemed at high-risk of complications with reservoir placements. Malleable prostheses result in a firm penis, which may be manually placed in an erect or flaccid state [48, 111, 214, 215].

There are two main surgical approaches for penile prosthesis implantation: penoscrotal and infrapubic [214-217]. The penoscrotal approach provides an excellent exposure, it affords proximal crural exposure if necessary, avoids dorsal nerve injury and permits direct visualisation of pump placement. However, with this approach, the reservoir is blindly placed into the retropubic space, which can be a problem in patients with a history of major pelvic surgery (mainly radical cystectomy). The infrapubic approach has the advantage of reservoir placement under direct vision, but the implantation of the pump may be more challenging, and patients are at a slightly increased risk of penile dorsal nerve injury. Revision surgery is associated with decreased outcomes and may be more challenging. Regardless of the indication, prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED based on appropriate consultation [48, 111, 214, 218-224]. In patients with favourable oncologic prognosis after RP for PCa, combination surgery for treatment of ED, with the implant of a penile prosthesis, and stress urinary incontinence (male sling or artificial urinary sphincter) is effective and durable and has an established, definitive role to address this problem [48, 111, 225-227]. A structured psychosexual counselling may improve sexual activities and erotic functions in both patients and their partners after penile implants [228].

3.1.4.4.1 Complications

The two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used 3-piece prosthesis (AMS 700CX/CXRTM and Coloplast Alpha ITM) resulted in mechanical failure rates of < 5% after five years of follow-up [111, 229, 230]. Careful surgical techniques with proper antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduces infection rates to 2-3% with primary implantation in low-risk patients and in high volume centres [231-233]. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast Titan™) [111, 231, 234-237]. Higher-risk populations include patients undergoing revision surgery, those with impaired host defenses

(immunosuppression, diabetes mellitus, spinal cord injury) or those with penile corporal fibrosis [17, 111, 214, 233, 238, 239]. Infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate replacement with a new prosthesis has been described using a washout protocol with successful salvages achieved in > 80% of cases [232, 233, 238]. The majority of revisions are secondary to mechanical failure and combined erosion or infection [236, 240]. 93% of cases are successfully revised, providing functioning penile prosthesis [231-233, 241, 242].

3.1.4.4.2 Conclusions third-line therapy

Penile implants are an attractive solution for patients who do not respond to more conservative therapies. There is sufficient evidence to recommend this approach in patients not responding to less-invasive treatments due to its high efficacy, safety and satisfaction rates.

3.1.4.5 Recommendations for the treatment of ED

Recommendations	LE	GR
Enact lifestyle changes and risk factor modification prior to or accompanying erectile	1a	A
dysfunction (ED) treatment.		
Start pro-erectile treatments at the earliest opportunity after radical prostatectomy.	1b	A
Treat a curable cause of ED first, when found.	1b	В
Use phosphodiesterase type 5 inhibitors (PDE5Is) as first-line therapy.	1a	A
Assess all patients for inadequate/incorrect prescriptions and poor patient education, since	3	В
they are the main causes of a lack of response to PDE5Is.		
Use vacuum erection devices as a first-line therapy in well-informed older patients with	4	С
infrequent sexual intercourse and comorbidity requiring non-invasive, drug-free management		
of ED.		
Use intracavernous injections as second-line therapy.	1b	В
Use implantation of a penile prosthesis as third-line therapy.	4	С

3.1.4.6 Follow-up

Follow-up is important in order to assess efficacy and safety of the treatment provided. It is also essential to assess patient satisfaction since successful treatment for ED goes beyond efficacy and safety. Physicians must be aware that there is no single treatment that fits all patients or all situations as described in detail in the previous section.

3.2 Premature ejaculation

3.2.1 Epidemiology/aetiology/pathophysiology

Although premature ejaculation (PE) is a common male sexual dysfunction, it is poorly understood. Patients are often unwilling to discuss their symptoms and many physicians do not know about effective treatments. As a result, patients may be misdiagnosed or mistreated [2].

3.2.1.1 Epidemiology

The major problem in assessing the prevalence of PE is the lack of an accurate (validated) definition at the time the surveys were conducted [243]. The highest prevalence rate of 31% (men aged 18-59 years) was found by the USA National Health and Social Life Survey (NHSLS) study [244]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years). It is, however, unlikely that the PE prevalence is as high as 20-30% based on the relatively low number of men who present for treatment of PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower [245]. According to the four PE subtypes proposed by Waldinger *et al.* [246], the prevalence rates were 2.3% (lifelong PE), 3.9% (acquired PE), 8.5% (natural variable PE) and 5.1% (premature-like ejaculatory dysfunction) [247]. An approximately 5% prevalence of acquired PE and lifelong PE in general populations is consistent with epidemiological data indicating that around 5% of the population have an ejaculation latency of less than 2 minutes [248].

3.2.1.2 Pathophysiology and risk factors

The aetiology of PE is unknown, with little data to support suggested biological and psychological hypotheses, including anxiety, penile hypersensitivity, and 5-HT receptor dysfunction [249]. In addition, the pathophysiology of PE is largely unknown. All the physiological events leading up to the forceful expulsion of sperm at the urethral meatus are not impaired in PE patients. A significant proportion of men with ED also experience PE

[250, 251]. High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED. According to the NHSLS, the prevalence of PE is not affected by age [244, 245], unlike ED, which increases with age. PE is not affected by marital or income status [244]. However, PE is more common in Black men, Hispanic men and men from Islamic backgrounds [252, 253] and may be higher in men with a lower educational level [244, 250]. Other risk factors may include a genetic pre-disposition [254], poor overall health status and obesity [244], prostate inflammation [255-257], thyroid hormone disorders [258], diabetes [259], emotional problems and stress [244, 260], and traumatic sexual experiences [244, 250]. In the only published study on risk modification/prevention strategies [261], successful eradication of causative organisms in patients with chronic prostatitis and PE produced marked improvements in intravaginal ejaculatory latency time (IELT) and ejaculatory control compared to untreated patients [262].

3.2.1.3 Impact of PE on QoL

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less frequent intercourse [263, 264]. However, the negative impact of PE extends beyond sexual dysfunction. Premature ejaculation can have a detrimental effect on self-confidence and the relationship with the partner, and may sometimes cause mental distress, anxiety, embarrassment and depression [263, 265]. Sex drive and overall interest in sex does not appear to be affected by PE [266]. However, the partner's satisfaction with the sexual relationship decreases with increasing severity of the man's condition [267]. Despite the possible serious psychological and QoL consequences of PE, few men seek treatment. In the Global Study of Sexual Attitudes and Behaviors survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems [250], with men more likely to seek treatment for ED than for PE [250]. In the Premature Ejaculation Prevalence and Attitudes survey, only 9% of men with self-reported PE consulted a doctor [245]. The main reasons for not discussing PE with their physician are embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE [268, 269]. Physicians need to encourage their patients to talk about PE.

3.2.2 Classification

There have previously been two official definitions of PE, neither of which have been universally accepted:

In the Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision (DSM-IV-TR), PE is defined as a 'persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity' [270]. This DSM definition has been recently updated in the DSM V edition [271].

The International Society for Sexual Medicine (ISSM) has adopted a completely new definition of PE which is the first evidence-based definition [272]. Premature ejaculation (lifelong and acquired) is a male sexual dysfunction characterised by the following:

- 1. Ejaculation that always or nearly always occurs prior to or within about 1 minute of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to about three minutes or less (acquired PE).
- 2. The inability to delay ejaculation on all or nearly all vaginal penetrations.
- 3. Negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.

Two more PE syndromes have been proposed [273]:

- 'Variable PE' is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- 'Subjective PE' is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.

The addition of these new types may aid patient stratification, diagnosis and treatment, but their exact role remains to be defined [274].

3.2.3 Diagnostic evaluation

Diagnosis of PE is based on the patient's medical and sexual history [275, 276]. History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual

stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED. Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection [251, 277]. Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE [278]. There are several overlapping definitions of PE, with four shared factors (Table 7), resulting in a multidimensional diagnosis [279].

Table 7: Common factors in different definitions of PE

Time to ejaculation assessed by IELT
Perceived control
Distress
Interpersonal difficulty related to the ejaculatory dysfunction

3.2.3.1 Intravaginal ejaculatory latency time

The use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE [280, 281]. Intravaginal ejaculatory latency time has a significant direct effect on perceived control over ejaculation, but not a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse [282]. In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation). In everyday clinical practice, self-estimated IELT is sufficient [283]. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity [284]. Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) on control over ejaculation and satisfaction with sexual intercourse (scale ranging from 0 = very poor to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all, to 4 = extremely). However, self-estimated IELT may be over-estimated by approximately one minute and therefore it must be carefully substituted with stopwatch-measured IELT while identifying men with the complaint of lifelong PE in a clinical setting [285]. Stopwatch-measured IELT is necessary in clinical trials. While IELT is an objective tool for PE assessment, a recent study reported that sexual satisfaction and distress correlated more strongly with the feeling of control than with the self-reported latency time [286].

3.2.3.2 *PE* assessment questionnaires

The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs [279]. Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT): five-item questionnaire based on focus groups and interviews from the USA, Germany and Spain. Assesses control, frequency, minimal stimulation, distress and interpersonal difficulty [287, 288]. A total score > 11 suggests a diagnosis of PE, a score of 9 or 10 suggests a probable diagnosis of PE while a score of < 8 indicates a low likelihood of PE.
- Arabic Index of Premature Ejaculation (AIPE): seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction for the patient and partner, anxiety or depression [289]. A cut-off score of 30 (range of scores 7-35) discriminated best PE diagnosis. Severity of PE was classified as severe (score: 7-13), moderate (score: 14-19), mild-to-moderate (score: 20-25) and mild (score: 26-30).

The most widely used tool is the PEDT. However, there is a low correlation between a diagnosis provided by PEDT and a self-reported diagnosis. A recent study reported that only 40% of men with PEDT-diagnosed PE and 19% of men with probable PE self-reported the condition [290]. Questionnaires are a significant step in simplifying the methodology of PE drug studies, although further cross-cultural validation is needed [291]. Other questionnaires used to characterise PE and determine treatment effects include the PEP [281], Index of Premature Ejaculation (IPE) [292] and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) [293]. Currently, their role is optional in everyday clinical practice.

3.2.3.3 Physical examination and investigations

Physical examination may be part of the initial assessment of men with PE. It may include a brief examination of the endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as endocrinopathy, Peyronie's disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended [275].

3.2.3.4 Recommendations for the diagnostic evaluation of PE

Recommendations	LE	GR
Perform the diagnosis and classification of premature ejaculation (PE) based on medical and sexual history, which should include assessment of intravaginal ejaculatory latency time (IELT) (self-estimated), perceived control, distress and interpersonal difficulty due to the ejaculatory dysfunction.	1a	A
Do not use stopwatch-measured IELT in clinical practice.	2a	В
Do not use patient-reported outcomes in clinical practice.	3	С
Include physical examination in the initial assessment of PE to identify anatomical abnormalities that may be associated with PE or other sexual dysfunctions, particularly erectile dysfunction.	3	С
Do not perform routine laboratory or neurophysiological tests. They should only be directed by specific findings from history or physical examination.	3	С

3.2.4 Disease management

In men for whom PE causes few, if any, problems, treatment is limited to psychosexual counselling and education. Before beginning treatment, it is essential to discuss the patient's expectations thoroughly. Furthermore, it is important firstly to treat, if present, ED and possibly prostatitis. Various behavioural techniques have been beneficial in treating PE and are indicated for patients uncomfortable with pharmacological therapy. In lifelong PE, behavioural techniques are not recommended for first-line treatment. They are time-intensive, require the support of a partner and can be difficult to perform. In addition, long-term outcomes of behavioural techniques for PE are unknown. Pharmacotherapy is the basis of treatment in lifelong PE. Dapoxetine is the only on-demand pharmacological treatment approved for PE in many countries except for the USA. All other medications used in PE are off-label indications. Chronic antidepressants including selective serotonin re-uptake inhibitors (SSRIs) and clomipramine, a tricyclic antidepressant and on-demand topical anaesthetic agents have consistently shown efficacy in PE. Long-term outcomes for pharmacological treatments are unknown. An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grades of recommendation are provided and a treatment algorithm is presented (Figure 4).

3.2.4.1 Psychological/behavioural strategies

Behavioural strategies mainly include the 'stop-start' programme developed by Semans [294] and its modification, the 'squeeze' technique, proposed by Masters and Johnson [295]:

- In the 'stop-start' programme, the partner stimulates the penis until the patient feels the urge to ejaculate. At this point, he instructs his partner to stop, waits for the sensation to pass and then stimulation is resumed.
- The 'squeeze' technique is similar but the partner applies manual pressure to the glans just before ejaculation until the patient loses his urge.

Both these procedures are typically applied in a cycle of three pauses before proceeding to orgasm. Behavioural strategies are based on the hypothesis that PE occurs because the man fails to appreciate the sensations of heightened arousal and to recognise the feelings of ejaculatory inevitability. Re-training may attenuate stimulus-response connections by gradually exposing the patient to progressively more intense and more prolonged stimulation, while maintaining the intensity and duration of the stimulus just below the threshold for triggering the response. There are several modifications of these techniques making comparison difficult.

Masturbation before anticipation of sexual intercourse is a technique used by younger men. Following masturbation, the penis is desensitised resulting in greater ejaculatory delay after the refractory period is over. In a different approach, the man learns to recognise the signs of increased sexual arousal and how to keep his level of sexual excitement below the intensity that elicits the ejaculatory reflex. Efficacy is similar to the 'stop-start' programme [296].

Psychological factors may be associated with PE and should be addressed in treatment. These factors mainly relate to anxiety, but could also include relationship factors [264]. The limited studies available suggest that behavioural therapy, as well as functional sexological treatment, lead to improvement in the duration of intercourse and sexual satisfaction [297, 298].

Overall, short-term success rates of 50-60% have been reported [297, 298], with limited evidence on the efficacy of these behavioural therapies on IELT improvement [299]. A double-blind, randomised, crossover

study showed that pharmacological treatment (chlomipramine, sertraline, paroxetine and sildenafil) resulted in greater IELT prolongation than behavioural therapy [300]. Furthermore, clinical experience suggests that improvements achieved with these techniques are generally not maintained long-term [301, 302]. Behavioural therapy may be most effective when used to 'add value' to medical interventions. Combination of dapoxetine and behavioural treatment was more effective than dapoxetine alone in patients with lifelong PE in a prospective, randomised trial [303]. Validated assessment instruments need to be used as end-points. Longer follow-up periods are necessary to confirm these findings.

3.2.4.2 Pharmacotherapy

3.2.4.2.1 Dapoxetine

Dapoxetine hydrochloride is a short-acting SSRI, with a pharmacokinetic profile suitable for on-demand treatment for PE. It has a rapid T_{max} (1.3 hours) and a short half-life (95% clearance rate after 24 hours) [304]. Dapoxetine has been investigated in 6,081 subjects to date [305]. It is approved for on-demand treatment of PE in European countries and elsewhere, but not in the USA. Both available doses of dapoxetine (30 mg and 60 mg) have shown 2.5- and 3.0-fold increases, respectively, in IELT overall, rising to 3.4- and 4.3-fold in patients with baseline average IELT < 0.5 minutes [306, 307]. In RCTs, dapoxetine, 30 mg or 60 mg one to two hours before intercourse, was effective from the first dose on IELT and increased ejaculatory control, decreased distress, and increased satisfaction. Dapoxetine has shown a similar efficacy profile in men with lifelong and acquired PE [307-309]. Treatment-related side-effects were dose-dependent and included nausea, diarrhoea, headache and dizziness. Side-effects were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects [283]. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [310]. Moreover, dapoxetine is found to be safer compared with other anti-depressants which are used for the treatment of PE [311].

Regarding a combination of PDE5Is with dapoxetine, the addition of dapoxetine to a given regimen of PDE5Is may increase the risk of possible prodromal symptoms that may progress to syncope compared to both PDE5Is inhibitors and SSRIs administered alone. Generally, when dapoxetine is co-administered with PDE5Is, it is well tolerated, with a safety profile consistent with previous phase 3 studies of dapoxetine alone [312]. A low rate of vasovagal syncope was reported in phase 3 studies. According to the summary of product characteristics, orthostatic vital signs (blood pressure and heart rate) must be measured prior to starting dapoxetine. No cases of syncope were observed in a post-marketing observational study, which had identified patients at risk for orthostatic reaction using the patient's medical history and orthostatic testing [313].

The mechanism of action of short-acting SSRIs in PE is still speculative. Dapoxetine resembles the antidepressant SSRIs in the following ways: the drug binds specifically to the 5-HT re-uptake transporter at subnanomolar levels, has only a limited affinity for 5-HT receptors and is a weak antagonist of the 1A-adrenoceptors, dopamine D1 and 5-HT2B receptors. The rapid absorption of dapoxetine might lead to an abrupt increase in extracellular 5-HT following administration that might be sufficient to overwhelm the compensating autoregulation processes. Does the mechanism of action of short-acting SSRIs differ from that of the conventional chronic SSRI mechanism of action? Either such agents do not cause the auto-receptor activation and compensation reported using chronic SSRIs, or these effects occur, but they simply cannot prevent the action of short-acting SSRIs [314].

3.2.4.2.2 Off-label use of antidepressants: SSRIs and clomipramine

Ejaculation is commanded by a spinal ejaculation generator [315, 316] under excitatory or inhibitory influences from the brain and the periphery [259]. 5-hydroxytryptamine (5-HT or serotonin) is involved in ejaculatory control, with its ejaculation-retarding effects likely to be attributable to activation of 5-HT1B and 5-HT2C receptors, both spinally and supraspinally. By contrast, stimulation of 5-HT1A receptors precipitates ejaculation [314].

Selective serotonin re-uptake inhibitors are used to treat mood disorders, but can delay ejaculation and are therefore widely used 'off-label' for PE. As for depression, SSRIs must be given for one to two weeks to be effective in PE [314]. Administration of chronic SSRIs causes prolonged increases in synaptic cleft serotonin, which desensitises the 5-HT1A and 5-HT1B receptors [317]. Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1973 as an effective PE treatment [318]. Selective serotonin re-uptake inhibitors have revolutionised treatment of PE, but they have also changed our understanding of PE since the first publication on paroxetine in 1970 [319]. Before dapoxetine, daily treatment with SSRIs was the first choice of treatment in PE. Commonly used SSRIs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar pharmacological mechanism of action.

Several SRs and meta-analyses of all drug treatment studies reported that, despite methodological problems in most studies, there still remained several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE [320, 321]. Nevertheless, despite significant increase in IELT, there are no data available concerning the PROs in PE patients treated with daily SSRIs. Based on this meta-analysis, SSRIs were expected to increase the geometric mean IELT by 2.6-fold to 13.2-fold. Paroxetine was found to be superior to fluoxetine, clomipramine and sertraline. Sertraline was superior to fluoxetine, whereas the efficacy of clomipramine was not significantly different from fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg; there was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective [322, 323].

Ejaculation delay may start a few days after drug intake, but it is more evident after one to two weeks since receptor de-sensitisation requires time to occur. Although efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after six to twelve months [318]. Common side-effects of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration; which are usually mild and gradually improve after two to three weeks [274, 306]. Decreased libido, anorgasmia, anejaculation and ED have also been reported.

Because of a theoretical risk of suicidal ideation or suicide attempts, caution is suggested in prescribing SSRIs to young adolescents with PE aged eighteen years or less, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation. Patients should be advised to avoid sudden cessation or rapid dose reduction of daily dosed SSRIs which may be associated with a SSRI withdrawal syndrome [283].

In one controlled trial, on-demand use of clomipramine (but not paroxetine), three to five hours before intercourse, was reported to be efficacious, though IELT improvement was inferior compared to daily treatment with the same drug [324]. However, on-demand treatment may be combined with an initial trial of daily treatment or concomitant low-dose daily treatment reducing adverse effects [325, 326]. Individual countries' regulatory authorities strongly advise against prescribing medication for indications if the medication in question is not licensed/approved and prescription of off-label medication may present difficulties for physicians.

3.2.4.2.3 Topical anaesthetic agents

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE [327]. Several trials [328, 329] support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis thereby delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation. A recent meta-analysis confirmed the efficacy and safety of these agents for the treatment of PE [330].

3.2.4.2.3.1 Lidocaine-prilocaine cream

In a randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream increased the IELT from one minute in the placebo group to 6.7 minutes in the treatment group [331]. In another randomised, doubleblind, placebo-controlled trial, lidocaine-prilocaine cream significantly increased the stop-watch-measured IELT from 1.49 to 8.45 minutes while no difference was recorded in the placebo group (1.67 to 1.95 minutes) [332]. Lidocaine-prilocaine cream (5%) is applied for 20-30 minutes prior to intercourse. Prolonged application of topical anaesthetic (30-45 minutes) may result in loss of erection due to numbness of the penis in a significant percentage of men [331]. A condom will prevent diffusion of the topical anaesthetic agent into the vaginal wall causing numbness in the partner.

Alternatively, the condom may be removed prior to sexual intercourse and the penis washed clean of any residual active compound. Although no significant side-effects have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any ingredient in the product.

An experimental aerosol formulation of lidocaine, 7.5 mg, plus prilocaine, 2.5 mg (Topical Eutectic Mixture for Premature Ejaculation [TEMPE]), was applied five minutes before sexual intercourse in 539 males. There was an increase in the geometric mean IELT from a baseline of 0.58 minutes to 3.17 minutes during three months of double-blind treatment; a 3.3-fold delay in ejaculation compared with placebo (p < 0.001) [333].

3.2.4.2.3.2 Tramadol

Tramadol is a centrally acting analgesic agent that combines opioid receptor activation and re-uptake inhibition

of serotonin and noradrenaline. Tramadol is readily absorbed after oral administration and has an elimination half-life of five to seven hours. For analgesic purposes, tramadol can be administered between three and four times daily in tablets of 50-100 mg. Side-effects were reported at doses used for analgesic purposes (up to 400 mg daily) and include constipation, sedation and dry mouth. Tramadol is a mild-opioid receptor agonist, but it also displays antagonistic properties on transporters of noradrenaline and 5-HT [334]. This mechanism of action distinguishes tramadol from other opioids, including morphine. However, in May 2009, the US Food and Drug Administration released a warning letter about tramadol's potential to cause addiction and difficulty in breathing [335].

A large, randomised, double-blind, placebo-controlled, multi-centre twelve week study was carried out to evaluate the efficacy and safety of two doses of tramadol (62 and 89 mg) by ODT in the treatment of PE [336]. A bioequivalence study had previously been performed that demonstrated equivalence between tramadol ODT and tramadol HCI. In patients with a history of lifelong PE and an IELT < 2 minutes, increases in the median IELT of 0.6 minutes (1.6-fold), 1.2 minutes (2.4-fold) and 1.5 minutes (2.5-fold) were reported for placebo, 62 mg of tramadol ODT, and 89 mg of tramadol ODT, respectively. It should be noted that there was no dose-response effect with tramadol. The tolerability during the twelve-week study period was acceptable. Several other studies also reported that tramadol exhibits a significant dose-related efficacy and side-effects over placebo for treatment of PE [337]. Moreover, the efficacy and safety of tramadol have been confirmed in SRs and meta-analyses [338, 339].

Tramadol has shown a moderate beneficial effect with a similar efficacy as dapoxetine. From what is known about the neuropharmacology of ejaculation and the mechanism of action of tramadol, the delaying effect on ejaculation could be explained by combined CNS μ -opioid receptor stimulation and increased brain 5-HT availability. However, efficacy and tolerability of tramadol would have to be confirmed in more patients and longer-term.

3.2.4.2.4 Other drugs

3.2.4.2.4.1 Phosphodiesterase type 5 inhibitors

There is only one well-designed, randomised, double-blind, placebo-controlled study comparing sildenafil to placebo [340]. Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and decreased the refractory time to achieve a second erection after ejaculation.

Several open-label studies showed that PDE5Is combined with an SSRI is superior to SSRI monotherapy:

- Sildenafil combined with paroxetine improved IELT significantly and satisfaction vs. paroxetine alone [341];
- Sildenafil combined with sertraline improved IELT and satisfaction significantly vs. sertraline alone [342];
- Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed [343];
- Tadalafil combined with paroxetine significantly improved IELT and satisfaction vs. paroxetine and tadalafil alone [344];
- Finally, sildenafil combined with behavioural therapy significantly improved IELT and satisfaction vs. behavioural therapy alone [345].

There are very limited data on the efficacy of other PDE5Is (tadalafil and vardenafil) [346, 347]. However, recent meta-analyses demonstrated that the combined use of SSRIs and PDE5Is may be more effective compared with SSRIs or PDE5Is monotherapy [348-350].

3.2.4.3 Summary of evidence on the epidemiology/aetiology/pathophysiology of PE

Summary of evidence	LE
Pharmacotherapy includes either dapoxetine on demand (a short-acting SSRI that is the only	1a
approved pharmacological treatment for premature ejaculation) or other off-label antidepressants, i.e.	
daily SSRIs and clomipramine, that are not amenable to on-demand dosing. With all antidepressant	
treatment for premature ejaculation, recurrence is likely after treatment cessation.	

3.2.4.4 Recommendations for the treatment of PE

		1
Recommendations	LE	GR
Treat erectile dysfunction, other sexual dysfunction or genitourinary infection (e.g. prostatitis	2a	В
first).		
Use pharmacotherapy as first-line treatment of lifelong premature ejaculation (PE).	1a	А
Use off-label topical anaesthetic agents as a viable alternative to oral treatment with selective	1b	А
serotonin re-uptake inhibitor (SSRI's).		
Use tramadol on demand as a weak alternative to SSRI's.	2a	В
Do not use PDE5Is in patients with premature ejaculation without erectile dysfunction.	3	С
Use psychological/behavioural therapies in combination with pharmacological treatment in the	3	С
management of acquired PE.		

Figure 4: Management of Premature Ejaculation*

Clinical diagnosis of premature ejaculation based on patient +/- partner history

- Time to ejaculation (IELT)
- Perceived degree of ejaculatory control
- Degree of bother/stress
- Onset and duration of PE
- Psychosocial/relationship issues
- Medical history
- Physical examination

Treatment of premature ejaculation

Patient counselling/education

Discussion of treatment options If PE is secondary to ED, treat ED first or

concomitantly

- Pharmacotherapy (recommended as first-line treatment option in lifelong PE)
 - o Dapoxetine for on-demand use (the only approved drug for PE)
 - Off-label treatments include chronic daily use of antidepressants (SSRIs or clomipramine) and topical anaesthetics or oral tramadol on demand
- Behavioural therapy, includes stop-start technique, squeeze and sensate focus
- Combination treatment

* Adapted from Lue et al. 2004 [351].

ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time; SSRI = selective serotonin receptor inhibitor.

3.3 Penile curvature

3.3.1 Congenital penile curvature

3.3.1.1 Epidemiology/aetiology/pathophysiology

Congenital curvature is rare. One well-performed study reports an incidence of less than 1% [352] while there

are reports from quality studies which claim that it is more common with prevalence rates of 4-10% in the absence of hypospadias [353].

Congenital penile curvature results from disproportionate development of the tunica albuginea of the corporal bodies and is not associated with urethral malformation. In the majority of cases the curvature is ventral but it can also be lateral and rarely dorsal.

3.3.1.2 Diagnostic evaluation

Taking a medical and sexual history is usually sufficient to establish the diagnosis of congenital penile curvature. Patients usually present after reaching puberty as the curvature becomes more apparent with erections, and severe curvature can make intercourse difficult or impossible. Physical examination during erection (autophotograph or after intracavernous injection of vasoactive drugs) is useful to document curvature and exclude other pathologies [354].

3.3.1.3 Disease management

The treatment of this disorder is surgical correction deferred until after puberty. Results from a recent survey suggest that men with possible untreated ventral penile curvature reported more dissatisfaction with penile appearance, increased difficulty with intercourse, and more unhealthy mental days therefore supporting correction of congenital penile curvature in childhood [355]. Surgical treatments for congenital penile curvature generally share the same principles as in Peyronie's disease (presented in detail in the next section). Nesbit procedure with excision of an ellipse of the tunica albuginea is the gold standard of treatment but many other techniques have been described and employed. Plication techniques are widely used including techniques producing a de-rotation of the corporal bodies [356]. A new modification of the latter technique has been suggested; Shaeer's corporal rotation enables correction of ventral congenital penile curvature, with minimal narrowing and shortening [357]. Most of the time, dissection of the dorsal neurovascular bundle is required in order to avoid loss of sensation and ischaemic lesions in the glans penis [358-360].

3.3.1.4 Summary of evidence and recommendation for congenital penile curvature

Summary of evidence	LE
Medical and sexual history are usually sufficient to establish the diagnosis of congenital penile	3
curvature. Physical examination during erection is useful for documentation of the curvature and	
exclusion of other pathologies.	
Surgery is the only treatment option which is deferred until after puberty and can be performed at any	3
time in adult life.	

Recommendation		GR
Use Nesbit and other plication techniques for the treatment of congenital penile curvature in		В
patients who undergo surgery.		

3.3.2 Peyronie's Disease

3.3.2.1 Epidemiology/aetiology/pathophysiology

3.3.2.1.1 Epidemiology

Epidemiological data on Peyronie's disease (PD) are limited. Prevalence rates of 0.4-9% have been published, with a higher prevalence in patients with ED and diabetes [361-368]. A recent, well conducted survey indicates that the prevalence of definitive and probable cases of PD in the US is 0.7% and 11%, respectively, suggesting that PD is an under-diagnosed problem [369]. The typical age of a patient with PD is 55-60 years.

3.3.2.1.2 Aetiology

The aetiology of PD is unknown. However, an insult (repetitive microvascular injury or trauma) to the tunica albuginea is the most widely accepted hypothesis on the aetiology of the disease [370]. A prolonged inflammatory response will result in the remodelling of connective tissue into a fibrotic plaque [370-372]. Penile plaque formation can result in curvature which, if severe, may prevent penetrative sexual intercourse.

3.3.2.1.3 Risk factors

The most commonly associated comorbidities and risk factors are diabetes, hypertension, lipid abnormalities, ischaemic cardiopathy, ED, smoking, and excessive consumption of alcohol [364, 368, 373, 374]. Dupuytren's contracture is more common in patients with PD affecting 9-39% of patients [365, 375-377] while 4% of patients with Dupuytren's contracture reported Peyronie's disease [376].
3.3.2.1.4 Pathophysiology

Two phases of the disease can be distinguished [378]. The first is the acute inflammatory phase, which may be associated with pain in the flaccid state or painful erections and a palpable nodule or plaque in the tunica of the penis; typically a penile curvature begins to develop. The second is the fibrotic phase (chronic phase) with the formation of hard palpable plaques that can be calcified, which also results in disease stabilisation and no further progressive curvature. With time, penile curvature is expected to worsen in 30-50% of patients or stabilise in 47-67% of patients, while spontaneous improvement has been reported by only 3-13% of patients [373, 379, 380]. Pain is present in 35-45% of patients during the early stages of the disease [381]. Pain tends to resolve with time in 90% of men, usually during the first twelve months after the onset of the disease [379, 380].

In addition to the physiological and functional alteration of the penis, affected men also suffer significant distress. Validated mental health questionnaires have shown that 48% of men with Peyronie's disease have mild or moderate depression, sufficient to warrant medical evaluation [382].

3.3.2.1.5 Summary of evidence on Peyronie's disease

Summary of evidence	LE
Peyronie's disease is a connective tissue disorder, characterised by the formation of a fibrotic lesion or	2b
plaque in the tunica albuginea, which leads to penile deformity.	
The contribution of associated comorbidities or risk factors (e.g. diabetes, hypertension, lipid	3
abnormalities and Dupuytren's contracture) to the pathophysiology of Peyronie's disease is still	
unclear.	
Two phases of the disease can be distinguished. The first phase is the acute inflammatory phase	2b
(painful erections, 'soft' nodule/plaque), and the second phase is the fibrotic/calcifying phase with	
formation of hard palpable plaques (disease stabilisation).	
Spontaneous resolution is uncommon (3-13%) and most patients experience disease progression (30-	2a
50%) or stabilisation (47-67%). Pain is usually present during the early stages of the disease but tends	
to resolve with time in 90% of men.	

3.3.2.2 Diagnostic evaluation

The aim of the initial evaluation is to provide information on the presenting symptoms and their duration (erectile pain, palpable nodules, curvature, length, rigidity, and girth) and erectile function status. It is mandatory to obtain information on the distress provoked by the symptoms and the potential risk factors for ED and Peyronie's disease. A disease-specific questionnaire (Peyronie's disease questionnaire (PDQ)) has been designed to collect data, and it has been validated for use in clinical practice [383]. Also, the utility of the PDQ for monitoring PD-specific psychosexual symptom severity, progression, and treatment response, both clinically and in trials of men with PD has been reported [384].

Major attention should be given to whether the disease is still active, as this will influence medical treatment or the timing of surgery. Patients who are still likely to have an active disease are those with a short symptom duration, pain during erection, or a recent change in penile curvature. Resolution of pain and stability of the curvature for at least three months are well-accepted criteria of disease stabilisation and patients' referral for surgical intervention when indicated [379].

The examination should start with a routine genitourinary assessment, which is then extended to the hands and feet for detecting possible Dupuytren's contracture or Ledderhose scarring of the plantar fascia [380]. Penile examination is performed to assess the presence of a palpable node or plaque. There is no correlation between plaque size and the degree of curvature [385]. Measurement of penile length during erection is important because it may have impact on the subsequent treatment decisions [386].

An objective assessment of penile curvature with an erection is mandatory. This can be obtained by a home (self) photograph of a natural erection (preferably) or using a vacuum-assisted erection test or an intracavernous injection using vasoactive agents [387]. Erectile function can be assessed using validated instruments such as the IIEF although this has not been validated in PD patients [65]. Erectile dysfunction is common in patients with PD (> 50%) but it is important to define whether it pre- or post-dates the onset of Peyronie's disease. It is mainly due to penile vascular disease [373], [385]. The presence of ED and psychological factors may impact on the treatment strategy [388].

Ultrasound measurement of the plaque's size is inaccurate and it is not recommended in everyday clinical practice [389]. Doppler US may be required for the assessment of vascular parameters [388].

3.3.2.2.1 Summary of evidence and recommendations for the diagnosis of Peyronie's disease

Summary of evidence	LE
Ultrasound (US) measurement of the plaque's size is inaccurate and operator dependent.	3
Doppler US is required to ascertain vascular parameters associated with ED.	2a

Recommendations	LE	GR
In the medical and sexual history of patients with Peyronie's disease, include duration of	2b	В
the disease, penile pain, change of penile deformity, difficulty in vaginal intromission due to		
deformity, and erectile dysfunction.		
In the physical examination, include assessment of palpable plaques, penile length, extent	2a	В
of curvature (self-photograph, vacuum-assisted erection test or pharmacological-induced		
erection) and any other possibly related diseases (Dupuytren's contracture, Ledderhose		
disease).		
Do not use Peyronie's disease specific questionnaire in everyday clinical practice.	2a	В
Do not use ultrasound (US) measurement of plaque size in everyday clinical practice.	3	С
Use Doppler US only in the case of diagnostic evaluation of erectile dysfunction, to ascertain	2a	В
vascular parameters associated with erectile dysfunction.		

3.3.2.3 Disease management

3.3.2.3.1 Non-operative treatment

Conservative treatment of Peyronie's disease is primarily focused on patients in the early stage of the disease [380, 390]. Several options have been suggested, including oral pharmacotherapy, intralesional injection therapy and other topical treatments (Table 8). Shockwave treatment of calcified plaques and clostridial collagenase (CCH) injection in patients with densely fibrotic or calcified plaques have also been suggested [378, 391]. Clostridium collagenase is the only drug approved for the treatment of PD by the FDA. No single drug has been approved by the EMA for the treatment of PD at this time. The results of the studies on conservative treatment for PD are often contradictory making it difficult to provide recommendations in the everyday, real-life setting. This is due to several methodological problems including uncontrolled studies, limited number of patients treated, short-term follow-up and different outcome measures [391]. Moreover, the efficacy of conservative treatment in distinct patient populations in terms of early (inflammatory) or late (fibrotic) phases of the disease is not yet available.

Table 8: Non-operative treatments for Peyronie's disease

Oral treatments

Intralesional treatments
Steroids
Verapamil
Clostridium collagenase
Interferon
Topical treatments
Verapamil
Iontophoresis
Extracorporeal shockwave treatment
Traction devices

3.3.2.3.1.1 Oral treatment

Vitamin E

Vitamin E (tocopherol, a fat-soluble compound that acts as a natural antioxidant to reduce the number of oxygen-free radicals produced in energy metabolism) is commonly prescribed by the majority of urologists at once or twice daily doses of 400 IU because of its wide availability, low cost and safety [392]. A double-blind, placebo-controlled crossover study failed to show a significant effect on penile deformity or plaque size [393]. Moreover, there is conflicting evidence as to the long-term cardiovascular effects of vitamin E usage at the large doses, which urologists use for penile deformity treatment [394].

Potassium para-aminobenzoate (Potaba[™])

Potassium para-aminobenzoate is thought to exert an antifibrotic effect through an increase in oxygen uptake by the tissues, a rise in the secretion of glycosaminoglycans, and an enhancement of the activity of monoamine oxidases [395]. Preliminary studies reported an improvement in penile curvature, penile plaque size, and penile pain during erection [396]. In a prospective double-blinded controlled study in 41 patients with PD, Potaba (12 g/day for twelve months) improved penile pain significantly, but not penile curvature or penile plaque size [397]. In another similar study in 103 patients with PD, Potaba decreased penile plaque size significantly, but had no effect on penile curvature or penile pain [398]. However, the pre-existing curvature under Potaba remained stable, suggesting a protective effect on the deterioration of penile curvature. Treatmentrelated adverse events are nausea, anorexia, pruritus, anxiety, chills, cold sweats, confusion and difficulty concentrating, but no serious adverse events were reported [399].

Tamoxifen

Tamoxifen is a non-steroidal oestrogen receptor antagonist modulating transforming growth factor β 1 (TGF β 1) secretion by fibroblasts. Preliminary studies reported that tamoxifen (20 mg twice daily for three months) improved penile pain, penile curvature, and reduced the size of penile plaque [400]. However, a placebocontrolled, randomised study (in only 25 patients, at a late stage of the disease with a mean duration of twenty months) using the same treatment protocol, failed to show any significant improvement in pain, curvature, or plaque size in patients with PD [401].

Colchicine

Colchicine has been introduced into the treatment of PD on the basis of its anti-inflammatory effect [402]. Clinical data should be interpreted with caution since they come from only uncontrolled studies. Preliminary results showed that half of the men given colchicine (0.6-1.2 mg daily for three to five months) found that painful erections and penile curvature improved, while penile plaque decreased or disappeared in 50% of 24 men [403]. In another study in 60 men (colchicine 0.5-1 mg daily for three to five months with escalation to 2 mg twice daily), penile pain resolved in 95% and penile curvature improved in 30% [402]. Similar results have been reported in another uncontrolled retrospective study in 118 patients [404]. Reported treatment-related adverse events with colchicine are gastrointestinal effects (nausea, vomiting, diarrhoea) that can be improved with dose escalation [402].

The combination of vitamin E and colchicine (600 mg/day and 1 mg every twelve hours, respectively for six months) in patients with early-stage PD resulted in significant improvement in plaque size and curvature, but not in pain compared to ibuprofen 400 mg/day for six months [405].

Acetyl esters of carnitine

Acetyl-L-carnitine and propionyl-L-carnitine are proposed to inhibit acetyl coenzyme-A and produce an anti-proliferative effect on human endothelial cells. This may eventually suppress fibroblast proliferation and collagen production, thus reducing penile fibrosis. In a randomised, double-blind study in 48 patients with early-stage PD, patients were randomised to acetyl-L-carnitine (1 g twice daily) compared to tamoxifen (20 mg twice daily). After three months, acetyl-L-carnitine was significantly more effective than tamoxifen in pain and curvature reduction and inhibition of disease progression, but not in penile plaque size reduction (both drugs significantly reduced plaque size) [406]. Tamoxifen induced significantly more side-effects.

Finally, the combination of intralesional verapamil (10 mg weekly for ten weeks) with propionyl-l-carnitine (2 g/ day for three months) significantly reduced penile curvature, plaque size, and disease progression compared to intralesional verapamil combined with tamoxifen (40 mg/day) for three months [407].

Pentoxifylline

Pentoxifylline is a non-specific phosphodiesterase inhibitor which down-regulates TGF β 1 and increases fibrinolytic activity [408]. Moreover, an increase of NO levels may be effective in preventing progression of PD

or reversing fibrosis [409]. Preliminary data from a case report showed that pentoxifylline (400 mg three times daily for six months) improved penile curvature and the findings on US of the plaque [409]. In another study in 62 patients with PD, pentoxifylline treatment for six months appeared to stabilise or reduce calcium content in penile plaques [410].

Phosphodiesterase type 5 inhibitors

The rationale for the use of PDE5Is in PD comes from animal studies showing that they can reduce the collagen/smooth muscle and collagen III/I ratios and increase the apoptotic index in the PD-like plaque [411]. In a retrospective controlled study, daily tadalafil (2.5 mg for six months) resulted in statistically significant (p < 0.05) resolution of septal scar in 69% of patients compared to 10% in the control group (no treatment). However, this study included patients with isolated septal scars without evidence of penile deformity [412]. Therefore, no recommendation can be given for PDE5Is in patients with PD.

3.3.2.3.1.2 Intralesional treatment

Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a particular agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure particularly when a dense or calcified plaque is present.

Steroids

Intralesional steroids are thought to act by opposing the inflammatory milieu responsible for Peyronie's plaque progression via inhibition of phospholipase A2, suppression of the immune response and by decreasing collagen synthesis [413]. In small, non-randomised studies, a decrease in penile plaque size and pain resolution was reported [414, 415]. In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistically significant changes in penile deformity, penile plaque size, and penile pain during erection were reported [416]. Adverse effects include tissue atrophy, thinning of the skin and immunosuppression [414].

Verapamil

The rationale for intralesional use of verapamil (a calcium channel antagonist) in patients with Peyronie's disease is based on in-vitro research [417, 418]. A number of studies have reported that intralesional verapamil injection may induce a significant reduction in penile curvature and plaque volume [419-423]. These findings suggested that intralesional verapamil injections could be advocated for the treatment of non-calcified acute phase or chronic plaques to stabilise disease progression or possibly reduce penile deformity, although large scale, placebo-controlled trials have not yet been conducted [422]. Side-effects are uncommon (4%). Minor side-effects include nausea, light-headedness, penile pain, and ecchymosis [422]. However, in the only randomised, placebo-controlled study, no statistically significant differences on plaque size, penile curvature, penile pain during erection or plaque 'softening' were reported [424]. Younger age and larger baseline penile curvature were found to be predictive of favourable curvature outcomes in a case-series study [425].

Clostridium collagenase

Clostridium collagenase (CCH) is a chromatographically purified bacterial enzyme that selectively attacks collagen, which is known to be the primary component of the PD plaque [426-428]. Clostridium collagenase is now approved by the FDA for PD in adult men with a palpable plaque and a curvature deformity of at least 30° at the start of therapy. Findings from two independent, double-blind, placebo controlled studies, reveal the efficacy and tolerability of CCH for improving the co-primary outcomes of physical penile curvature and the psychological subject reported PD symptom bother domain of the PDQ in adults with PD. Participants were given up to four treatment cycles of CCH or placebo and were then followed for 52 weeks. Overall, of the 551 treated men with CCH 60.8% were global responders compared with 29.5% of the 281 patients who received the placebo. The most commonly reported side-effects were penile pain, penile swelling, and ecchymosis at the site of injection [427]. The data from these two large RCTs were analysed by subgroups including: baseline penile curvature deformity, PD duration, degree of penile calcification, and baseline erectile function severity with better results in patients with less than 60° of curvature, more than two years of evolution, no calcification in the plaque and good erectile function [429].

Clostridium collagenase was approved by the EMA in 2014 specifying that CCH should be administered by a healthcare professional who is experienced in the treatment of male urological diseases. The Risk Management Plan (RMP) requires participating healthcare professionals to be certified within the programme by enrolling and completing training in the administration of CCH treatment for PD [430].

A recent paper which studied a pooled safety analysis of 1,044 CCH-treated patients from six clinical studies showed that the majority of Peyronie's patients experienced at least one adverse reaction (Global Safety database, 92.5%). Most adverse reactions were localised to the penis or groin and the majority of these events were of a mild or moderate severity. Most of these resolved within fourteen days of the injection. The adverse reaction profile was similar after each injection, regardless of the number of injections administered. The most frequently reported treatment-related adverse events in the clinical trials in subjects with PD (Global Safety database) were penile hematoma (50.2%), penile pain (33.5%), penile swelling (28.9%) and injection site pain (24.1%) [431].

Interferon

Interferon α -2b has been shown to decrease fibroblast proliferation, extracellular matrix production and collagen production from fibroblasts and improve the wound healing process from PD plaques in-vitro [432]. Intralesional injections (5 x 106 units of interferon α -2b in 10 mL saline, two times per week for twelve weeks) significantly improved penile curvature, plaque size and density, and pain compared to placebo [433, 434]. Side-effects include myalgias, arthralgia, sinusitis, fever and flu-like symptoms. They can be effectively treated with non-steroidal anti-inflammatory drugs before interferon injection.

Hyaluronic Acid

In a prospective, single-arm, multicentre pilot study, 65 patients underwent a ten week cycle of weekly intraplaque injections with hyaluronic acid. Plaque size significantly decreased, penile curvature decreased in 37%, as well as overall sexual satisfaction and seems preferably indicated in the early (active) phase of the disease [435].

3.3.2.3.1.3 Topical treatments

Topical verapamil

There is no evidence that topical treatments applied to the penile shaft result in adequate levels of the active compound within the tunica albuginea. Verapamil gel has been used in this context [436]. Iontophoresis - now known as transdermal electromotive drug administration (EMDA) - has been introduced to try and overcome limitations on the local uptake of the drugs themselves. Small studies using lontophoresis with verapamil 5 mg and dexamethasone 8 mg resulted in inconsistent results [437, 438].

H-100 Gel

H-100 Gel is composed of nicardipine, superoxide dismutase and emu oil. Twenty-two patients (PD twelve months duration) were studied in a prospective randomised, double-blind, placebo-controlled study. H-100 showed significant improvement in all PD parameters at six months: mean stretched penile length increase (22.6%, P = 0.0002), mean curvature reduction (40.8%, P = 0.0014), and mean pain level reduction (85.7%, P = 0.004). Placebo group showed no significant improvement except for mean stretched penile length increase (6.8%, P = 0.009). Crossover patients from placebo to H-100 showed significant improvement in all parameters: mean stretched penile length increase (17.5%, P = 0.000007), mean curvature reduction (37.1%, P = 0.006), and mean pain level reduction (40%, P = 0.17). Treatment was well tolerated. A self-limited rash was the only side-effect in three patients. Statistically significant improvements in flaccid-stretched penile length, curvature and pain suggest that H-100 is a safe and possibly effective non-invasive, topically applied treatment for acute phase PD [439].

Extracorporeal shockwave treatment

The mechanism of action involved in shockwave treatment (ESWT) for PD is still unclear, but there are two hypotheses. In the first hypothesis, shockwave therapy works by directly damaging and remodelling the penile plaque. In the second hypothesis, shockwave lithotripsy increases the vascularity of the area by generating heat resulting in an inflammatory reaction, with increased macrophage activity causing plaque lysis and eventually leading to plaque resorption [440]. Most uncontrolled studies failed to show significant improvements in patients with PD [441-443]. In a prospective, randomised, double-blind, placebo-controlled study, four weekly treatment sessions of ESWT, with each session consisting of 2,000 focused shockwaves, resulted in significant improvement only for penile pain [444].

Traction devices

The application of continuous traction in Dupuytren's contracture increases the activity of degradative enzymes [445]. This initially leads to a loss of tensile strength and ultimately to solubilisation. It is followed by an increase in newly synthesised collagen [445]. This concept has been applied in an uncontrolled study, including ten patients with Peyronie's disease. The FastSize Penile Extender was applied as the only treatment for two to eight hours per day for six months [111]. Reduced penile curvature of 10-40° was found in all men with an

average reduction of 33% (range: 51-34°). The stretched penile length increased 0.5-2.0 cm and the erect girth increased 0.5-1.0 cm, with a correction of hinge effect in four out of four men. Treatment can be uncomfortable and inconvenient due to use of the device for two to eight hours daily for an extended period, but has been shown to be tolerated by highly motivated patients [376]. There were no serious adverse events, including skin changes, ulcerations, hypoesthesia or diminished rigidity.

In another prospective study, there was a significant reduction in penile curvature (mean 20° reduction). Erectile function and erection hardness also improved significantly. The percentage of patients who were not able to achieve penetration decreased from 62% to 20% (p < 0.03). Importantly, the need for surgery was reduced in 40% of patients who would otherwise have been candidates for surgery and simplified the complexity of the surgical procedure (from grafting to plication) in one in three patients [446].

3.3.2.3.1.4 Summary of evidence and recommendations for non-operative treatment of Peyronie's disease

Summary of evidence	LE
Conservative treatment for PD is primarily aimed at treating patients in the early stage of the disease.	3
Oral treatment with potassium para-aminobenzoate may result in a significant reduction in penile	1b
plaque size and penile pain as well as penile curvature stabilisation.	
Intralesional treatment with verapamil may induce a significant reduction in penile curvature and	1b
plaque volume.	
Intralesional treatment with CCH showed significant decreases in the deviation angle, plaque width	1b
and plaque length.	
Intralesional treatment with interferon may improve penile curvature, plaque size and density, and pain.	1b
Topical verapamil gel 15% may improve penile curvature and plaque size.	1b
Iontophoresis with verapamil 5 mg and dexamethasone 8 mg may improve penile curvature and	1b
plaque size.	
Extracorporeal shockwave treatment does not improve penile curvature and plaque size, but it may be	1b
offered for penile pain.	
Intralesional treatment with steroids is not associated with significant reduction in penile curvature,	2b
plaque size or penile pain.	
plaque size or penile pain.	

Recommendations	LE	GR
Use conservative treatment in patients not fit for surgery or when surgery is not acceptable to	3	С
the patient.		
Do not use extracorporeal shockwave treatment to improve penile curvature and reduce	1b	С
plaque size.		
Use penile traction devices and vacuum devices to reduce penile deformity and increase penile	2b	С
length.		
Do not use intralesional treatment with steroids to reduce penile curvature, plaque size or pain.	1b	В
Do not use oral treatment with vitamin E and tamoxifen for significant reduction in penile	2b	В
curvature or plaque size.		
Do not offer other oral treatments (acetyl esters of carnitine, pentoxifylline, colchicine).	3	С

3.3.2.3.2 Surgical treatment

Although conservative treatment for PD should resolve painful erections in most men, only a small percentage will experience any significant straightening of the penis. The aim of surgery is to correct curvature and allow satisfactory intercourse. Surgery is indicated in patients with penile curvature that does not allow satisfactory intercourse and which is associated with sexual bother [90]. Patients must have a stable disease for at least three months, although a six to twelve month period has also been suggested [447].

The potential aims and risks of surgery should be discussed with the patient so that he can make an informed decision. Specific issues that should be mentioned during this discussion are the risks of penile shortening, ED, penile numbress, the risk of recurrent curvature, the potential for palpation of knots and stitches underneath the skin, and the potential need for circumcision at the time of surgery [378]. Two major types of repair may be considered for both congenital penile curvature and PD: penile shortening and penile lengthening procedures [448].

Penile shortening procedures include the Nesbit wedge resection and the plication techniques performed on the convex side of the penis. Penile lengthening procedures are performed on the concave side of the penis and require the use of a graft. They aim to minimise penile shortening caused by Nesbit or plication of the tunica albuginea or correct complex deformities. Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) is considered the standard approach for all types of procedures [448]. However, recent data suggest that circumcision is not always necessary e.g. in cases where the foreskin is normal pre-operatively [449]. Finally, in patients with PD and ED not responding to medical treatments, surgical correction of the curvature with concomitant penile prosthesis implantation should be considered [450].

Selection of the most appropriate surgical intervention is based on penile length assessment, curvature severity and erectile function status, including response to pharmacotherapy in cases of ED [378]. Patient expectations from surgery must also be included in the pre-operative assessment. There are no standardised questionnaires for the evaluation of surgical outcomes [90]. Data from well-designed prospective studies are scarce, with a low level of evidence. Most data are mainly based on retrospective studies, typically non-comparative and non-randomised, or on expert opinion [378, 451].

3.3.2.3.2.1 Penile shortening procedures

In 1965, Nesbit was the first to describe the removal of the tunical ellipses opposite a non-elastic corporal segment to treat congenital penile curvature [452]. Fourteen years later, this technique became a successful treatment option, also for PD [453]. This operation is based on a 5-10 mm transverse elliptical excision of the tunica albuginea or approximately 1 mm for each 10° of curvature [448]. The overall short- and long-term results of the Nesbit operation are excellent. Complete penile straightening is achieved in more than 80% of patients [454]. Recurrence of the curvature and penile hypoesthesia are uncommon (about 10%) and the risk of post-operative ED is minimal [448, 455]. Penile shortening is the most commonly reported outcome of the Nesbit procedure [455]. However, shortening of only 1-1.5 cm has been reported for about 85% of patients, which is rarely the cause of post-operative sexual dysfunction [453, 456]. Patients often perceive the loss of length as greater than it actually is [454, 455]. It is therefore advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whatever the technique used. Only one modification of the Nesbit procedure has been described (partial thickness shaving instead of conventional excision of a wedge of tunica albuginea) [457].

Plication procedures are based on the same principle as the Nesbit operation but are simpler to perform. Many of them have been described as Nesbit modifications in the older literature. They are based on single or multiple longitudinal incisions on the convex side of the penis closed in a horizontal way, applying the Heineke-Miculicz principle, or plication is performed without making an incision [458-463]. Another modification has been described as the '16 dot' technique with minimal tension under local anaesthesia [464]. The use of non-absorbable sutures reduced recurrence of the curvature. Results and satisfaction rates are similar to the Nesbit procedure [448]. However, numerous different modifications have been described and the level of evidence is not sufficient to recommend one method over the other.

3.3.2.3.2.2 Penile lengthening procedures

Tunical lengthening procedures entail an incision in the short (concave) side of the tunica to increase the length of this side, creating a tunical defect, which is covered by a graft. However, plaque removal may be associated with high rates of post-operative ED due to venous leak [465].

Devine and Horton introduced dermal grafting in 1974 [466]. Since then, a variety of grafting materials and techniques have been reported (Table 10) [467-481]. Unfortunately, the ideal material for grafting has yet to be identified. In addition, grafting procedures are associated with ED rates as high as 25%. Despite excellent initial surgical results, graft contracture and long-term failures resulted in a 17% re-operation rate [482].

Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. The Saphenous vein is the most common vein draft used, followed by dorsal penile vein [448]. In the first case, a secondary incision for graft harvesting is avoided. Post-operative curvature (20%), penile shortening (17%) and graft herniation (5%) have been reported after vein graft surgery [472, 477, 480]. Tunica vaginalis is relatively avascular, easy to harvest and has little tendency to contract due to its low metabolic requirements [470].

Dermal grafts are commonly associated with contracture resulting in recurrent penile curvature (35%), progressive shortening (40%), and a 17% re-operation rate at ten years [483]. Cadaveric pericardium (Tutoplast®) offers good results by coupling excellent tensile strength and multi-directional elasticity/expansion

by 30% [481]. In a retrospective telephone interview, 44% of patients with pericardium grafting reported recurrent curvature, although most of them continued to have successful intercourse and were pleased with their outcomes [481, 483].

Small intestinal submucosa (SIS, a collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine) has been shown to promote tissue-specific regeneration, and supports the growth of endothelial cells. Small intestinal submucosa acts as a scaffold to promote angiogenesis, host cell migration and differentiation, resulting in tissue structurally and functionally similar to the original. It has been used successfully to repair severe chordee and Peyronie's disease, without significant contraction or histological alterations, but data are limited [478].

More recently the use of buccal mucosa grafts (BMG) has been advocated. Buccal mucosa grafts provided excellent short-term results, suggested by the fast return of spontaneous erections and prevented shrinkage, which is the main cause of graft failure. It also proved to be safe and reproducible, thus representing a valuable treatment option for PD [469].

Grafting by collagen fleece (TachoSil[®]) in PD is feasible and promising. Major advantages are decreased operative times and easy application. Moreover, an additional haemostatic effect is provided [484].

Tunical incision, preferably with grafting, offers an excellent surgical option for men with curvatures over 60° as well as patients with an hour-glass deformity and good erectile function that are willing to risk a higher rate of post-operative ED [485]. The presence of pre-operative ED, the use of larger grafts, age more than 60 years, and ventral curvature are considered poor prognostic factors for functional outcome after grafting surgery [450]. Although the risk for penile shortening is significantly less compared to the Nesbit or plication procedures, it is still an issue and patients must be informed accordingly [448]. The use of geometric principles introduced by Egydio helps to determine the exact site of the incision, and the shape and size of the defect to be grafted [471].

The use of a penile extender device on an eight to twelve hour daily regimen has been advocated as an effective and safe treatment for loss of penile length in patients operated on for PD [486].

3.3.2.3.2.3 Penile prosthesis

Penile prosthesis (PP) implantation is typically reserved for the treatment of PD in patients with ED, especially when they are non-responders to PED5Is [376]. Although all types of penile prosthesis can be used, the implantation of inflatable penile prosthesis seems to be most effective in these patients [480].

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion. In cases of severe deformity, intra-operative 'modelling' of the penis over the inflated cylinders (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) has been introduced as an effective treatment [487, 488]. If there is a residual curvature of less than 30°, no further treatment is recommended, as the prosthesis will act as a tissue expander and will result in complete correction of curvature after a few months of cycling the prosthesis [487]. While this technique is effective in most patients, a Nesbit/plication procedure or plaque excision/incision and grafting may be required in order to achieve adequate straightening [489-491].

The risk of complications (infection, malformation, etc.) is not increased compared to the general population. However, a small risk of urethral perforation (3%) has been reported in patients with 'modelling' over the inflated prosthesis [488].

In selected cases of end-stage PD with ED and significant penile shortening, a lengthening procedure, which involves simultaneous PP implantation and penile length restoration, such as the 'sliding' technique, can be considered but only in the hands of experienced high-volume surgeons [492].

	Tunical shortening	procedures	Tunical lengthening procedures
	Nesbit	Plication	Grafts
Penile shortening	4.7-30.8%	41-90%	0-40%
Penile straightening	79-100%	58-100%	74-100%
Persistent or recurrent curvature	4-26.9%	7.7-10.6%	0-16.7%
Post-operative erectile dysfunction	0-13%	0-22.9%	0-15%
Penile hypoesthesia	2-21%	0-21.4%	0-16.7%
Technical modifications	1	At least 3	Many types of grafts
			and techniques used

Table 10: Results of surgical treatments for Peyronie's disease (data from different, non-comparable studies) [453, 455-481, 483, 485]

Treatment algorithm

The decision on the most appropriate surgical procedure to correct penile curvature is based on pre-operative assessment of penile length, the degree of the curvature and erectile function status. If the degree of curvature is less than 60°, penile shortening is acceptable and the Nesbit or plication procedures are usually the method of choice. This is typically the case for congenital penile curvature. If the degree of curvature is over 600 or is a complex curvature, or if the penis is significantly shortened in patients with a good erectile function (with or without pharmacological treatment), then a grafting procedure is feasible. If there is ED, which is not responding to pharmacological treatment, the best option is the implantation of an inflatable PP, with or without an associated procedure over the penis (modelling, plication or even grafting plus the prosthesis). The treatment algorithm is presented in Figure 5.

Figure 5: Treatment algorithm for Peyronie's disease

ED = erectile dysfunction; US = ultrasound.

The results of the different surgical approaches are presented in Table 10. It must be emphasised that there are no RCTs available addressing surgery in PD. The risk of ED seems to be greater for penile lengthening procedures [378, 448]. Recurrent curvature implies either failure to wait until the disease has stabilised, a re-activation of the condition following the development of stable disease, or the use of re-absorbable sutures that lose their strength before fibrosis has resulted in acceptable strength of the repair [120]. Accordingly, it is recommended that only non-absorbable sutures or slowly re-absorbed absorbable sutures be used. Although with non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin but this issue may be alleviated by the use of slowly re-absorbed absorbable sutures [455]. Penile numbness is a potential risk of any surgical procedure involving mobilisation of the dorsal neurovascular bundle. This will usually be a neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is a dorsal deformity, the procedure most likely to induce this complication is a lengthening (grafting) procedure [448].

3.3.2.3.2.4 Recommendations for the surgical treatment of penile curvature

Recommendations	LE	GR
Perform surgery only when Peyronie's disease has been stable for at least three months	3	С
(without pain or deformity deterioration), which is usually the case after twelve months from the		
onset of symptoms, and intercourse is compromised due to deformity.		
Prior to surgery, assess penile length, curvature severity, erectile function (including response	3	С
to pharmacotherapy in case of erectile dysfunction) and patient expectations.		
Use tunical shortening procedures, especially plication techniques as the first treatment	2b	В
option for congenital penile curvature and for Peyronie's disease with adequate penile length,		
curvature < 60° and absence of special deformities (hour-glass, hinge).		
Use grafting techniques for patients with Peyronie's disease and normal erectile function, with	2b	В
no adequate penile length, curvature > 60° and presence of special deformities (hour-glass,		
hinge).		
Use penile prosthesis implantation, with or without any additional procedure (modelling,	2b	В
plication or grafting), in Peyronie's disease patients with erectile dysfunction not responding to		
pharmacotherapy		

3.4 Priapism

3.4.1 Ischaemic (Low-Flow or Veno-Occlusive) Priapism

3.4.1.1 Epidemiology/aetiology/pathophysiology

Ischaemic priapism is the most common form of priapism, accounting for more than 95% of all priapism episodes [493, 494]. It is usually painful, with a rigid erection characterised clinically by absent or reduced intracavernous arterial inflow (often proximally there is a compensated high velocity picture with little flow distally). In ischaemic priapism, there are time-dependent alterations in the corporal metabolic environment, progressively leading to hypoxia, hypercapnia, glucopenia and acidosis [495].

Ischaemic priapism beyond four hours is considered the same as a compartment syndrome, characterised by supraphysiological pressure within the closed space of the corpora cavernosa, which severely compromises cavernous circulation. Emergency medical intervention is required to minimise potential irreversible consequences, such as smooth muscle necrosis, corporal fibrosis and permanent ED [496, 497]. The duration of priapism represents the most significant predictor for the development of ED. In this context, interventions beyond 48-72 hours of onset may help to relieve the erection and pain, but have little benefit in preventing long-term ED.

Histologically, by twelve hours, corporal smooth muscle biopsies show interstitial oedema, progressing to destruction of the sinusoidal endothelium, exposure of the basement membrane and thrombocyte adherence at 24 hours. At 48 hours, thrombi can be found in the sinusoidal spaces and smooth muscle necrosis with fibroblast-like cell transformation is evident [422]. In terms of the pathophysiology (Table 11), no specific cause can be identified in the majority of cases [494, 498]. However, ischaemic priapism can be associated with sickle cell disease, haematological dyscrasias, neoplastic syndromes, and with the use of a number of pharmacological agents. Ischaemic priapism may occur (0.4-35%) after intracavernous injections of erectogenic agents [194, 494, 496, 499, 500]. The risk is highest with papaverine-based combinations, while the risk of priapism is < 1% following prostaglandin E1 injection [501].

Since their introduction on the market, a few cases of priapism have been described in men who have taken PDE5Is [494]. Most of these men however, had other risk factors for priapism, and it is unclear whether PDE5Is alone can cause ischaemic priapism [494]. Since most men who experienced priapism following PDE5I use had additional risk factors for ischaemic priapism, PDE5I use is usually not regarded a risk factor in itself. Sickle cell disease is the most common cause in childhood, accounting for 63% of the cases. It is the primary aetiology in 23% of adult cases [501], with a lifetime probability of developing ischaemic priapism of 29-42% in men with sickle cell disease [501-503] (LE: 4). Mechanisms of sickle cell disease associated priapism may involve dysfunctional NO synthase and Rho-associated protein kinase (ROCK) signaling, and increased oxidative stress associated with nicotinamide adenine dinucleotide phosphate (NADPH) oxidase mediated signaling [504].

Priapism resulting from metastatic or regional infiltration is rare and usually reflects an infiltrative process [505]. As such, the recommendations for pharmacological treatment are unlikely to work and certainly all of these men should have a magnetic resonance imaging (MRI) scan of the penis and be offered supportive care and medical intervention for their primary cancer.

Priapism in children is extremely rare and is most commonly related to malignancy, haematological or otherwise. The investigative focus should be on identifying any underlying causes.

Partial priapism, or idiopathic partial segmental thrombosis of the corpus cavemosum, is a very rare condition. It is an often classified as subtype of priapism limited to a single crura but ischaemia does not develop, rather it is a thrombus within the corpus. Its aetiology is unknown, but bicycle riding, trauma, drug usage, sexual intercourse, haematological diseases and α -blockers have been associated with partial priapism [506]. There may be a congenital web in the corpora which poses a risk factor [507].

Table 11: Potential causative factors for ischaemic priapism

Idiopathic

Haematological dyscrasias (sickle cell disease, thalassemia, leukaemia; multiple myeloma, Hb Olmsted
variant, fat emboli during hyperalimentation, haemodialysis, glucose-6-phosphate dehydrogenase deficiency,
Factor V Leiden mutation)
Infections (toxin-mediated) (i.e. scorpion sting, spider bite, rabies, malaria)
Metabolic disorders (i.e. amyloidosis, Fabry's disease, gout)
Neurogenic disorders (i.e. syphilis, spinal cord injury, cauda equina syndrome, autonomic neuropathy, lumbar
disc herniation, spinal stenosis, cerebrovascular accident, brain tumour, spinal anaesthesia)
Neoplasms (metastatic or regional infiltration) (i.e. prostate, urethra, testis, bladder, rectal, lung, kidney)
Medications
- Vasoactive erectile agents (i.e. papaverine, phentolamine, prostaglandin E1/alprostadil, combination of
intracavernous therapies)
- α -adrenergic receptor antagonists (i.e. prazosin, terazosin, doxazosin, tamsulosin)
- Anti-anxiety agents (hydroxyzine)
- Anticoagulants (heparin, warfarin)
- Antidepressants and antipsychotics (i.e. trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine,
risperidone, olanzapine, chlorpromazine, thiorizadine, phenothiazines)
- Antihypertensives (i.e. hydralazine, guanethidine, propranolol)
- Hormones (i.e. gonadotropin-releasing hormone, testosterone)
- Recreational drugs (i.e. alcohol, marijuana, cocaine [intranasal and topical], crack, cocaine)

3.4.1.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of ischaemic priapism

LE
1b
1b
2a
1a

3.4.1.2 Classification

Ischaemic priapism is a persistent erection marked by rigidity of the corpora cavernosa and by little or no cavernous arterial inflow [494]. The patient typically complains of penile pain and examination reveals a rigid erection. Resolution of ischaemic priapism is characterised by return to a flaccid non-painful state. However, in many cases, persistent penile oedema, ecchymosis and partial erections can occur and may mimic unresolved priapism. The partial erections may reflect reactive hyperaemia and are sometimes misdiagnosed as persistent priapism. When left untreated, resolution may take days and ED invariably results.

3.4.1.3 Diagnostic evaluation

Figure 6: Differential diagnosis of priapism

3.4.1.3.1 History

Taking a comprehensive history is the mainstay in priapism diagnosis [494, 508]. The medical history must include asking about a history of sickle cell disease or any other haematological abnormality [9, 509] and a history of pelvic, genital or perineal trauma. The sexual history must include complete details of the duration of the erection, the presence and degree of pain, prior medical drug use, any previous history of priapism and erectile function prior to the last priapism episode (Table 12). The history can help to determine the underlying subtype of priapism (Table 13). Ischaemic priapism is classically associated with progressive penile pain and the erection is rigid.

Table 12: Key points in taking the history of priapism (adapted from Broderick et al. [494])

Duration of erection
Presence and degree of pain
Previous episodes of priapism and method of treatment
Current erectile function, especially the use of any erectogenic therapies prescription or nutritional supplements
Medications and recreational drugs
Sickle cell disease, haemoglobinopathies, hypercoagulable states
Trauma to the pelvis, perineum, or penis

3.4.1.3.2 Physical examination

In ischaemic priapism, the corpora are fully rigid and tender, but the glans penis is soft. The patient complains of pain. Pelvic examination may reveal cases of underlying malignancy.

3.4.1.3.3 Laboratory testing

Laboratory testing should include a complete blood count, white blood count with blood cell differential, platelet count and coagulation profile to assess anaemia and detect haematological abnormalities [494, 508].

Blood aspiration from the corpora cavernosa shows dark ischaemic blood (Table 13) (LE: 2b). Blood gas analysis is essential to differentiate between ischaemic and arterial priapism (Table 14). Further laboratory

testing should be directed by history, clinical and laboratory findings. These may include specific tests for the diagnosis of sickle cell anaemia or other haemoglobinopathies (e.g. haemoglobin electrophoresis) or urine and plasma toxicological studies when there is suspected use of recreational psychoactive drugs.

3.4.1.3.4 Penile imaging

Colour Doppler US of the penis and perineum is recommended and can differentiate ischaemic from arterial priapism as an alternative or adjunct to blood gas analysis [510-512] (LE: 2b). Scanning of the penis should be performed before corporal blood aspiration in ischaemic priapism.

Examination of the penile shaft and perineum is recommended. In ischaemic priapism there will be an absence of blood flow in the cavernous arteries. The return of the cavernous artery waveform will result in successful detumescence [494, 512, 513]. After aspiration, a reactive hyperaemia may develop with a high arterial flow proximally that may mislead the diagnosis as arterial priapism.

The role of MRI in the diagnostic evaluation of priapism is controversial. It may be helpful in cases of ischaemic priapism to assess the viability of the corpora cavernosa and the presence of penile fibrosis. In a prospective study in 38 patients with ischaemic priapism, the sensitivity of MRI in predicting non-viable smooth muscle was 100%, as confirmed by corporal biopsy [514]. In this study, all patients with viable smooth muscle on MRI maintained erectile function on clinical follow-up (LE: 3).

Table 13: Key findings in priapism (adapted from Broderick et al. [494])

	Ischaemic priapism	Arterial priapism
Corpora cavernosa fully rigid	Usually	Seldom
Penile pain	Usually	Seldom
Abnormal penile blood gas	Usually	Seldom
Haematological abnormalities	Usually	Seldom
Recent intracorporeal injection	Sometimes	Sometimes
Perineal trauma	Seldom	Usually

Table 14: Typical blood gas values (adapted from Broderick et al. [494])

Source	pO ₂ (mmHg)	pCO ₂ (mmHg)	рН
Normal arterial blood (room air)	> 90	< 40	7.40
[similar values are found in arterial priapism]			
Normal mixed venous blood (room air)	40	50	7.35
Ischaemic priapism (first corporal aspirate)	< 30	> 60	< 7.25

3.4.1.3.5 Recommendations for the diagnosis of ischaemic priapism

Recommendations	GR
Take a comprehensive history for diagnosis which can help to determine the underlying type of	В
priapism.	
Include physical examination of the genitalia, the perineum and the abdomen in the diagnostic	В
evaluation.	
For laboratory testing, include complete blood count, white blood count with blood cell differential,	В
platelet count and coagulation profile. Direct further laboratory testing by history, clinical and	
laboratory findings. In children with priapism, perform a complete evaluation of all possible causes.	
Analyse blood gas of blood aspirated from the penis for the differentiation between ischaemic and	В
arterial priapism.	
Perform colour duplex ultrasound of the penis and perineum for the differentiation between ischaemic	В
and arterial priapism as an alternative or adjunct to blood gas analysis.	
In cases of prolonged ischaemic priapism, use magnetic resonance imaging of the penis to predict	В
smooth muscle viability and confirm erectile function restoration.	
Perform selected pudendal arteriogram when embolisation is planned for the management of arterial	В
priapism.	

3.4.1.4 Disease management

Acute ischaemic priapism is a medical emergency. Urgent intervention is compulsory (LE: 4), and should follow a stepwise approach. The aim of any treatment is to restore penile flaccidity, without pain, in order to prevent damage to the corpora cavernosa.

Figure 7: Treatment of ischaemic priapism

The treatment is sequential and the physician should move on to the next stage if the treatment fails.

Initial conservative measures

- Local anaesthesia of the penis
- Insert wide bore butterfly () through the glans into the corpora cavernosa
- Aspiration cavernosal blood until bright red arterial blood is obtained

Cavernosal irrigation

• Irrigate with 0.90% w/v saline solution

Intracavernosal therapy

- Inject intracavernosal adrenoceptor agonist
- Current first-line therapy is phenylephrine* with aliquots of 200 µg being injected every 3-5 minutes until detumescence is achieved (Maximum dose of phenylephrine is 1mg within 1 hour)*

Surgical therapy

- Surgical shunting
- · Consider primary penile implantation if priapism has been present for more than 36 hours

(*) The dose of phenylephrine should be reduced in children. It can result in significant hypertension and should be used with caution in men with cardiovascular disease and monitoring of pulse, blood pressure and electrocardiogram (ECG) is advisable in all patients during administration and for 60 minutes afterwards. Its use is contraindicated in men with a history of cerebro-vascular disease and significant hypertension.

3.4.1.4.1 First-line treatments

First-line treatments in ischaemic priapism of more than four hours duration are strongly recommended before any surgical treatment (LE: 4). Conversely, first-line treatments initiated beyond 72 hours while relieving the priapism have little documented benefit in terms of long-term potency preservation (LE: 4).

Historically, several first-line treatments have been described including exercise, ejaculation, ice packs, cold baths, and cold water enemas [494]. However, there is lack of evidence of benefit for such measures.

Partial priapism usually resolves spontaneously with analgesic treatment while surgical intervention is rarely needed [515].

3.4.1.4.1.1 Penile anaesthesia/systemic analgesia

It is possible to perform blood aspiration and intracavernous injection of a sympathomimetic agent without any anaesthesia. However, anaesthesia may be necessary when there is severe penile pain. While it is recognised that the anaesthesia may not alleviate the ischaemic pain, cutaneous anaesthesia will facilitate subsequent therapies. The treatment options for penile anaesthesia/systemic analgesia include:

- dorsal nerve block;
- circumferential penile block;
- subcutaneous local penile shaft block;
- oral conscious sedation (for paediatric patients).

3.4.1.4.1.2 Aspiration ± irrigation with 0.9% w/v saline solution

The first intervention for an episode of priapism lasting more than four hours consists of corporal aspiration (LE: 4) to drain stagnant blood from the corporal bodies, making it possible to relieve the compartment syndrome-like condition of the penis. Blood aspiration may be performed with intracorporeal access either through the glans or via percutaneous needle access on the lateral aspect of the proximal penile shaft, using a 16 G or 18 G angiocatheter or butterfly needle. The needle must penetrate the skin, the subcutaneous tissue and the tunica albuginea to drain the corpus cavernosum (LE: 4).

Some clinicians use two angiocatheters or butterfly needles at the same time to accelerate drainage, as well as aspirating and irrigating simultaneously with a saline solution [502] (LE: 4). Aspiration should be continued until fresh red, oxygenated, blood is aspirated (LE: 4).

This approach has up to a 30% chance of resolving the priapism. There are insufficient data to determine whether aspiration followed by saline intracorporeal irrigation is more effective than aspiration alone (LE: 4).

3.4.1.4.1.3 Aspiration ± irrigation with 0.90% w/v saline solution in combination with intracavernous injection of pharmacological agents.

This combination is currently considered the standard of care in the treatment of ischaemic priapism [4, 494, 516] (LE: 4). Pharmacological agents include sympathomimetic drugs or α -adrenergic agonists. Options for intracavernous sympathomimetic agents include phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine and metaraminol with a resolution rate of up to 80%. [494, 516-524] (LE: 2b). The use of intracavernous adrenaline injection alone has also been sporadically reported [525].

Phenylephrine

Phenylephrine is currently the drug of choice due to its high selectivity for the α -1-adrenergic receptor, without concomitant β -mediated inotropic and chronotropic cardiac effects [517, 521, 522] (LE: 4).

Phenylephrine is diluted in normal saline to a concentration of 100-500 µg/mL. Usually 200 µg are given every three to five minutes directly into the corpus cavernosum. Maximum dosage is 1 mg within one hour (LE: 4). A lower concentration or volume is applicable for children and patients with severe cardiovascular disease (LE: 4).

Phenylephrine use has potential cardiovascular side-effects [494, 516-518, 521, 522] and it is recommended that blood pressure and pulse are monitored every fifteen minutes for an hour after the injection. This is particularly important in older men with existing cardiovascular diseases. After injection, the puncture site should be compressed and the corpora cavernosa massaged to facilitate drug distribution.

The potential treatment-related side-effects of intracavernous phenylephrine (and other sympathomimetic agents) include headache, dizziness, hypertension, reflex bradycardia, tachycardia and palpitations, irregular cardiac rhythms and sporadic subarachnoid haemorrhage [39]. Monitoring of blood pressure and pulse with ECG should be performed during intracavernous administration of sympathomimetic agents.

Overall, the administration of intracavernous sympathomimetic agents is contraindicated in patients suffering from malignant or poorly controlled hypertension and in those who are concurrently taking monoamine oxidase inhibitors (LE: 4).

Etilephrine

Etilephrine is the second most widely used sympathomimetic agent, administered by intracavernous injection at a concentration of 2.5 mg in 1-2 mL normal saline [518] (LE: 3).

Methylene blue

Methylene blue is a guanylate cyclase inhibitor, which may be a potential inhibitor of endothelial-mediated cavernous relaxation. It has therefore been suggested for treating short-term pharmacologically induced priapism [526, 527] (LE: 3). Methylene blue, 50-100 mg [526], should be injected intracavernously and left for five minutes. It is then aspirated and the penis compressed for an additional five minutes [527]. Treatment-related side-effects include a transient burning sensation and blue discolouration of the penis.

Adrenaline

Intracavernosal adrenaline (dosage of 2 mL of 1/100,000 adrenaline solution up to five times over a 20-minute period [525]), has been used in patients with ischaemic priapism due to an intracavernous injection of vasoactive agents. A success rate of over 50% after a single injection, with an overall success rate of 95% with repeated injections is achieved (LE: 3).

Oral terbutaline

Oral terbutaline is a β -2-agonist with minor β -1 effects and some α -agonist activity. A dose of 5 mg has been suggested to treat prolonged erections lasting more than 2.5 hours, after intracavernous injection of vasoactive agents, although the mechanism of action is not yet fully understood [528-530] (LE: 1b). Its main use is in the prevention of recurrent episodes of prolonged erection. Terbutaline should be given cautiously in patients with coronary artery disease, increased intravascular fluid volume, oedema and hypokalaemia [530].

Drug	Dosage/Instructions for use
Phenylephrine	• Intracavernous injection of 200 µg every three to five minutes.
	Maximum dosage is 1 mg within one hour.
	• The lower doses are recommended in children and patients with severe
	cardiovascular disease.
Etilephrine	Intracavernosal injection at a concentration of 2.5 mg in 1-2 mL normal
	saline.
Methylene blue	Intracavernous injection of 50-100 mg, left for five minutes. It is then
	aspirated and the penis compressed for an additional five minutes.
Adrenaline	Intracavernous injection of 2 mL of 1/100,000 adrenaline solution up to
	five times over a twenty-minute period.
Terbutaline	Oral administration of 5 mg for prolonged erections lasting more than 2.5
	hours, after intracavernous injection of vasoactive agents.

Table 15: Medical treatment	of	ischaemic	priapism
-----------------------------	----	-----------	----------

Management of sickle cell disease related priapism

Rapid intervention is essential (LE: 4) and the general approach is similar to that described in other cases of ischaemic priapism and should be co-ordinated with a haematologist [531-533] (LE: 4).

However, as with other haematological disorders, other therapeutic practices may also need to be implemented [531, 533, 534]. Specific measures for sickle cell disease related priapism include intravenous hydration and parental narcotic analgesia while preparing the patient for aspiration and irrigation. In addition, supplemental oxygen administration and alkalinisation with bicarbonate can be helpful [503, 532].

Exchange blood transfusion has also been proposed, with the aim of increasing the tissue delivery of oxygen [535]. The transfused blood should be HbS negative, Rh and Kell antigen matched [536]. However, the evidence is inconclusive as to whether exchange transfusion itself helps to resolve the priapism in these men. It should also be noted that several reports suggest that this treatment may result in serious neurological sequelae [537]. Because of these considerations, the routine use of this therapy is not recommended (LE: 4).

3.4.1.4.2 Second-line treatments

Second-line intervention typically refers to surgical intervention in the form of penile shunt surgery and should only be considered when conservative management options fail (LE: 4). There is no evidence detailing the amount of time allowed for first-line treatment before moving on to surgery. Consensus recommendations suggest a period of at least one hour of first-line therapy prior to moving to surgery (LE: 4). A number of clinical indicators suggest failure of first-line treatment including continuing corporal rigidity, cavernosal acidosis and anoxia, absence of cavernosal artery inflow by penile colour duplex US, and elevated intracorporal pressures by pressure monitoring (LE: 4).

3.4.1.4.3 Penile shunt surgery

Penile shunt surgery aims to produce an exit for ischaemic blood from the corpora cavernosa thereby allowing the restoration of normal circulation within these structures. Accordingly, any shunt creates an opening in the tunica albuginea, which may communicate with either the glans, the corpus spongiosum or a vein for blood drainage [494, 516, 538].

In general, the type of shunt procedure chosen is according to the surgeon's preference and familiarity with the procedure. It is conventional for distal shunt procedures to be tried before proximal shunting is considered (LE: 4). Cavernous biopsy has been used to identify smooth muscle necrosis (which, if present, would suggest that shunting is likely to fail) although this is mainly performed for medico-legal purposes and patient counselling.

It is important to assess the success of surgery by either direct observation or by investigation (e.g. cavernous blood gas testing, penile colour duplex US) (LE: 4) [494, 516].

The recovery rates of erectile function in men undergoing shunt surgery for prolonged erections are low and directly relate to the duration of the priapism [539, 540]. Priapism for more than 36 hours appears to irreversibly impair erectile tissue both structurally and functionally [539]. In general, shunt procedures undertaken after this time period may only serve to limit pain without any benefit for erectile function (LE: 4) [541, 542].

Four categories of shunt procedures have been reported [4, 494, 538, 542]. The limited available data preclude any recommendation for one procedure over another based on outcome (LE: 4).

Percutaneous distal (corpora-glanular) shunts

Winter's procedure: this procedure uses a Trucut biopsy needle to create a fistula between the glans penis and each corpora cavernosa [4, 494, 501, 543, 544] (LE: 3). Post-operative sequelae are uncommon [545]. Winter's shunt is easy to perform, but has been reported as the least successful operation to create a distal shunt [540].

Ebbehoj's technique: this technique involves making multiple tunical incision windows between the glans and each tip of the corpus cavernosum by means of a size 11 blade scalpel passed several times percutaneously [4, 494, 543, 546, 547] (LE: 3).

T-Shunt: this technique involves performing a bilateral procedure using a size 10 blade scalpel placed vertically through the glans just lateral to the meatus until fully within the corpus cavernosum. The blade is then rotated 90° away from the urethra and pulled out [4, 494, 543, 548] (LE: 3). This is followed by a tunneling procedure using a size 8 dilator inserted through the glans and into the corpora which can be performed using US for guidance, mainly in order to avoid urethral injury [548].

Open distal (corpora-glanular) shunts

Al-Ghorab's procedure: this procedure consists of an open bilateral excision of circular cone segments of the distal tunica albuginea via the glans penis, along with a subsequent glans closure by means of a running suture with absorbable material [4, 494, 543, 549, 550] (LE: 3).

Burnett's technique (Snake manoeuvre): a modification of the Al-Ghorab corpora-glanular shunt surgery involves the retrograde insertion of a 7/8 Hegar dilator into the distal end of each corpus cavernosum through the original Al-Ghorab glanular excision. After removal of the dilator from the corpus cavernosum, blood evacuation is facilitated by manual compression of the penis sequentially from a proximal to distal direction. After detumescence, the glans penis skin is closed as in the Al-Ghorab procedure [4, 494, 543, 551, 552] (LE: 3). Reported complications include wound infection, penile skin necrosis and a urethrocutaneous fistula [552].

Open proximal (corporospongiosal) shunts

Quackles's technique: through a trans-scrotal or perineal approach, a proximal open shunt technique creates a communication between the corpus cavenosum and the corpus spongiosum. The most frequent complications include an unwanted urethro-cavernous fistula and urethral stricture or the development of cavernositis [4, 494, 538, 553]. The risk of urethral injury is less with a perineal approach to the bulb of the corpus spongiosum (LE: 3).

Vein anastomoses/shunts

Grayhack's procedure: this mobilises the saphenous vein below the junction of the femoral vein and anastomoses the vein end-to-side onto the corpus cavernosum. Venous shunts may be complicated by saphenofemoral thrombus formation and by pulmonary embolism [4, 494, 554-556] (LE: 3).

Immediate surgical prosthesis implantation

Refractory, therapy-resistant, acute ischaemic priapism or episodes lasting more than 48-72 hours usually result in complete ED, possibly along with major penile deformity. In these cases, immediate penile prosthesis surgery has been suggested [557-560] (LE: 3).

The immediate insertion of a malleable penile prosthesis has been recommended to avoid the difficulty and complications of delayed surgery in the presence of corporal fibrosis. Potential complications that could compromise immediate penile prosthesis implantation include distal erosion and cavernositis [557, 559], along with a small rate of revision surgery [557]. Early surgery also offers the opportunity to maintain penile size, and prevent penile curvature due to cavernosal fibrosis. The prosthesis can be exchanged for an inflatable prosthesis at a later date which also allows upsizing of the implant cylinders [561].

Currently, there are no clear indications for immediately implanting a penile prosthesis in a man with acute ischaemic priapism [516]. Relative indications include [494] (LE: 4):

- ischaemia that has been presented for more than 36 hours [560];
- failure of aspiration and sympathomimetic intracavernous injections;
- failure of distal and proximal shunting (although in delayed cases, implantation might be considered ahead of shunt surgery);
- Magnetic resonance imaging or corporal biopsy evidence of corporal smooth muscle necrosis [494, 557] (LE: 4).

Surgery for non-acute sequelae after ischaemic priapism

Structural changes may occur after ischaemic priapism including cavernosal tissue necrosis and fibrosis with consequent penile scarring, megalophallic deformities, penile shortening, and occasional penile loss, [538, 557, 562, 563]. Erectile dysfunction is also often observed [494, 564]. Unfortunately, these outcomes can still occur despite apparently successful first-line or second-line treatment.

Prosthesis implantation is occasionally indicated in sickle cell patients with severe ED since other therapeutic options such as PDE5Is and intracavernous injections are avoided as they may provoke a further priapism event [494, 516]. In severe corporal fibrosis, semi-rigid prosthetic devices are preferable to inflatable implants [557, 565] (LE: 3). Following severe priapism that has resulted in penile destruction with complicated deformities or even loss of penile tissue, penile reconstruction and concomitant prosthesis implant may be considered [566] (LE: 3).

3.4.1.5 Summary of evidence and recommendations for the treatment of ischaemic priapism

Summary of evidence	LE
Intervene rapidly for ischaemic priapism, which is an emergency condition.	2b
Treatment aims to restore painless penile flaccidity, in order to prevent chronic damage to the corpora	3
cavernosa.	
Erectile function preservation is directly related to the duration of ischaemic priapism.	2b
Phenylephrine is the recommended drug due to its favourable safety profile on the cardiovascular	2b
system compared to other drugs. Phenylephrine is usually diluted in normal saline with a	
concentration of 100-500 µg/mL and given in 200 µg doses every three to five minutes directly into the	
corpus cavernosum. Maximum dosage is 1 mg within one hour. Patients at high cardiovascular risk	
should be given lower doses. Patient monitoring is highly recommended.	
The efficacy of shunt procedures for ischaemic priapism is questionable. Diagnose smooth muscle	3
necrosis when needed with cavernous biopsy. No clear recommendation on one type of shunt over	
another can be given.	
Erectile dysfunction is inevitable in prolonged cases or priapism. Implantation of penile prosthesis at a	2b
later stage can be difficult due to severe corporal fibrosis.	

Recommendations	GR
Start management of ischaemic priapism as early as possible (within four to six hours) and follow a	В
stepwise approach.	
First, decompress the corpora cavernosa by penile aspiration until fresh red blood is obtained.	С
In priapism secondary to intracavernous injections of vasoactive agents, replace blood aspiration with	С
intracavernous injection of a sympathomimetic drug as the first step.	
In priapism that persists despite aspiration, proceed to the next step, which is intracavernous injection	В
of a sympathomimetic drug.	
In cases that persist despite aspiration and intracavernous injection of a sympathomimetic drug,	С
repeat these steps several times before considering surgical intervention.	
Treat ischaemic priapism due to sickle cell anaemia in the same fashion as idiopathic ischaemic	В
priapism. Provide other supportive measures (intravenous hydration, oxygen administration with	
alkalisation with bicarbonates, blood exchange transfusions), but do not delay initial treatment to the	
penis.	
Proceed to surgical treatment only when blood aspiration and intracavernous injection of	С
sympathomimetic drugs have failed or for priapism events lasting < 72 hours.	
Perform distal shunt surgical procedures first followed by proximal procedures in case of failure.	С
Discuss the immediate implantation of a penile prosthesis with the patient in cases of priapism	В
presenting > 36 hours after onset, or in cases for which all other interventions have failed.	

3.4.1.6 Follow-up

Follow-up of ischaemic priapism after successful treatment should include modification of risk factors (if any) in order to avoid a new event and assessment of erectile function since it may be severely compromised especially after surgical treatment with a shunt. Penile fibrosis is usually easily identified with clinical examination of the penis.

3.4.2 Arterial (high-flow or non-ischaemic) priapism

3.4.2.1 Epidemiology/aetiology/pathophysiology

Epidemiological data on arterial priapism are almost exclusively derived from small case series [494, 512, 513, 567, 568]. The most frequent cause of high-flow priapism is blunt perineal or penile trauma [569]. The injury results in a laceration in the cavernosal artery leading to a high-flow fistula between the artery and the lacunar spaces of the sinusoidal tissue [568]. This unregulated flow results in a persistent erection, and has been proposed to occur via a mechanism that involves stimulation of endothelial NO synthase by the turbulent blood flow [570]. Partial erections are enhanced after sexual stimulation, as the trabecular smooth muscle fully relaxes, activating the corporal veno-occlusive mechanism [568, 571].

There is often a delay between the injury and the development of the priapism that may be up to two to three weeks [571]. This has been suggested to reflect either spasm or ischaemic necrosis of the injured artery, with the fistula only developing as the spasm resolves or when the ischaemic segment blows out.

Occasional cases are associated with metastatic malignancy to the penis [572, 573], with acute spinal cord injury [574] and occasionally following intracavernous injections or aspiration due to a lacerated cavernous artery or branch [575, 576]. Under these circumstances, it may complicate low-flow priapism. It has also been reported to occur following internal urethrotomy [577] and a Nesbit procedure [578]. Although sickle cell disease is usually associated with low-flow priapism, occasional cases of high-flow priapism have been reported [579].

3.4.2.1.1 Summary of Evidence on the epidemiology, aetiology and pathophysiology of arterial priapism

Summary of evidence	LE
Arterial priapism usually occurs after blunt perineal or penile trauma.	

3.4.2.2 Classification

Arterial priapism is a persistent erection caused by unregulated cavernous arterial inflow [494]. The patient typically reports an erection that is not fully rigid and is not associated with pain although fully rigid erections may occur with sexual stimulation.

3.4.2.3 Diagnostic evaluation

3.4.2.3.1 History

A comprehensive history is also mandatory in arterial priapism diagnosis and follows the same principles as described in Table 12. Arterial priapism is suspected when there is no pain and erections are not fully rigid (Table 13). It can be associated with full erections under sexual stimulation and when there is a history of coital trauma or blunt trauma to the penis. The onset of post-traumatic high-flow priapism in adults and children may be delayed by hours to days following the initial injury. Sexual intercourse is usually not compromised.

3.4.2.3.2 Physical examination

In arterial priapism, the corpora are tumescent but not fully rigid (Table 13). Abdominal, penile and perineal examination may reveal evidence of trauma.

3.4.2.3.3 Laboratory testing

Blood aspiration from the corpora cavernosa shows bright red arterial blood in arterial priapism, while blood is dark in ischaemic priapism (Table 13) (LE: 2b). Blood gas analysis is essential to differentiate between arterial and ischaemic priapism (Table 14).

3.4.2.3.4 Penile imaging

Colour duplex US of the penis and perineum is recommended and can differentiate arterial from ischaemic priapism as an alternative or adjunct to blood gas analysis [510-512] (LE: 2b). Examination of the penile shaft and perineum is recommended. In arterial priapism US will show turbulent flow at the fistula, which helps to localise the site of trauma since patients with arterial priapism have normal to high blood velocities in the cavernous arteries.

A selective pudendal arteriogram can reveal a characteristic blush at the site of the injury to the cavernosal artery in arterial priapism [580, 581]. However, due to its invasiveness it should be reserved for the management of arterial priapism, when embolisation is being considered [494, 508] (LE: 3).

The role of MRI in the diagnostic evaluation of priapism is controversial. In arterial priapism, its role is limited since the small penile vessels and arteriovenous fistulae cannot be easily demonstrated [582].

3.4.2.3.5 Recommendations for the diagnosis of arterial priapism The same recommendations as in section 3.4.1.3.5 apply.

3.4.2.4 Disease management

The management of high-flow priapism is not an emergency because the penis is not ischaemic. Definitive management can therefore be considered and should be discussed with the patient so that they understand the risks and complications of treatment [494, 508] (LE: 3).

3.4.2.4.1 Conservative management

This may include applying ice to the perineum or site-specific perineal compression [512, 567, 583, 584]. It is an option in all cases, particularly children [585] (LE: 3). The fistula occasionally closes spontaneously. Even in those cases when it does not, the response to a sexual stimulus does allow for intercourse. Androgen deprivation therapy (leuprolide injections, bicalutamide and ketoconazole) has been reported in case series to enable closure of the fistula reducing spontaneous and sleep-related erections [586]. However, sexual dysfunction due to these treatments must be considered.

Blood aspiration is not helpful for the treatment of arterial priapism and the use of α -adrenergic antagonists is not recommended due to potential severe adverse effects, e.g. transfer of the drug into the systemic circulation.

3.4.2.4.1.1 Selective arterial embolisation

Selective arterial embolisation can be performed using either an autologous clot [587-589], gel foam or sponge [588, 590], or more permanent substances, such as coils [588, 590-592] or acrylic glue [593] (LE: 3). Success rates of up to 89% have been reported [594] in relatively small, non-randomised studies. There are no robust data to demonstrate the relative merits of the different substances. At least theoretically, the use of an autologous clot has some attractions. It temporarily seals the fistula, but when the clot is lysed, the arterial damage has usually resolved and the blood flow of the penis can return to normal. The use of a permanent device, such as a coil, would permanently block an artery and may lead to adverse effects upon spontaneous sexual function. Other potential complications include penile gangrene, gluteal ischaemia, cavernositis and perineal abscess [494, 595].

Following percutaneous embolisation, a follow-up is appropriate within one to two weeks. Assessment by clinical examination and by colour duplex US can determine whether the embolisation has been successful [511]. If there is doubt, a repeat arteriogram is required. Recurrence rates of 7-27% after a single treatment with embolisation have been reported [588, 589, 596] (LE: 3). In a few cases, repeat embolisation is necessary. Sexual function following embolisation can be adversely affected although there is full restoration of potency in around 80% of men [596, 597] (LE: 3).

Embolisation in children, although reportedly successful, is technically challenging and requires treatment within a specialist paediatric vascular radiology department [520, 598].

3.4.2.4.2 Surgical management

Selective ligation of the fistula through a transcorporeal approach under the guidance of colour duplex US is possible [4, 509, 599]. Surgery is technically challenging and may pose significant risks, mainly ED due to accidental ligation of the cavernous artery instead of the fistula. It is rarely performed and should only be considered when there are contraindications for selective embolisation, no availability of the technique or embolisation failure (LE: 4).

3.4.2.4.3 Summary of evidence and recommendations for the treatment of arterial priapism

Summary of evidence	LE
Because high-flow priapism is not an emergency, perform definitive management at the discretion of	
the treating physician.	
Conservative management with the use of ice applied to the perineum or site-specific perineal	3
compression may be successful particularly in children. The use of androgen deprivation therapy may	
enable closure of the fistula reducing spontaneous and sleep-related erections.	
Artery embolisation, using temporary or permanent substances, has high success rates. No	3
definitive statement can be made on the best substance for embolisation in terms of sexual function	
preservation.	
Repeat the procedure for the recurrence of arterial priapism following selective artery embolisation.	2b
Reserve selective surgical ligation of the fistula as a last treatment option when embolisation has	3
failed.	

Recommendations	GR
Because high-flow priapism is not an emergency, perform definitive management at the discretion of	В
the treating physician.	
Manage conservatively with the use of ice applied to the perineum or site-specific perineal	С
compression as the first step, especially in children. Use androgen deprivation therapy only in adults.	
Perform selective artery embolisation, using temporary or permanent substances.	В
Repeat the procedure for the recurrence of arterial priapism following selective artery embolisation.	В
Reserve selective surgical ligation of the fistula as a final treatment option when embolisation has	С
failed.	

3.4.2.4.4 Follow-up

Follow-up after successful treatment of arterial priapism should include assessment of erectile function and clinical examination to identify signs of recurrence especially after embolisation.

3.4.3 Stuttering (recurrent or intermittent) priapism

3.4.3.1 Epidemiology/aetiology/pathophysiology

Robust epidemiological studies of stuttering priapism are lacking [8, 600]. However, recurrent priapism episodes are common in men with sickle cell disease (42-64%) [601, 602] while in adolescents and young men the incidence of priapism is 35%, of whom 72% have a history of stuttering priapism [8].

The aetiology of stuttering priapism is similar to that of ischaemic priapism. While sickle cell disease is the most common cause, idiopathic cases and cases due to a neurological disorder have been reported. Moreover, men who have suffered from an acute ischaemic priapic event, especially one which has been prolonged (more than four hours) are at risk for developing stuttering priapism [564].

Recently, several studies have proposed alternative mechanisms including inflammation, cellular adhesion, NO metabolism, vascular reactivity and coagulation [494, 504, 532, 603, 604].

3.4.3.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of stuttering priapism

Summary of evidence	LE
Stuttering priapism is similar to ischaemic priapism in that it is low-flow, ischaemic and, if left	3
untreated would result in significant penile damage, with sickle cell disease being the most common	
cause. But the cause can also be idiopathic and in rare cases may be due to a neurological disorder.	

3.4.3.2 Classification

Stuttering priapism, also termed intermittent or recurrent priapism, is a distinct condition that is characterised by repetitive and painful episodes of prolonged erections. Erections are self-limited with intervening periods of detumescence [532, 603]. These are analogous to repeated episodes of low-flow (or ischaemic) priapism. The duration of the erectile episodes is generally shorter than in ischaemic priapism [4]. The frequency and/ or duration of these episodes is variable and a single episode can sometimes progress into a major ischaemic priapic episode.

3.4.3.3 Diagnostic evaluation

3.4.3.3.1 History

A comprehensive history is mandatory and follows the same principles as described in Table 12. There is a history of recurrent episodes of prolonged erections. The onset of the priapic episodes usually occurs during sleep and detumescence does not occur upon waking. Many of these priapic episodes are painful and may be the reason that the patient seeks medical help.

3.4.3.3.2 Physical examination

Erections are painful and the penis is rigid as in ischaemic priapism, but the duration of events is usually shorter. Between erections the penis is usually normal, but in some cases signs of fibrosis can be found. Rarely, the penis may become enlarged, a condition known as megalophallus.

3.4.3.3.3 Laboratory testing

Laboratory testing follows the same principles as in the two other types of priapism. It is recommended to identify possible causes and should be directed by history, clinical and laboratory findings.

3.4.3.3.4 Penile imaging

There are no specific findings for stuttering priapism. Colour duplex US of the penis and perineum and MRI are recommended and can differentiate arterial from ischaemic type of priapism.

3.4.3.3.5 Recommendations for the diagnosis of stuttering priapism

The same recommendations as described in section 3.4.1.3.5 apply. Stuttering priapism is a recurrent or intermittent type of ischaemic priapism.

3.4.3.4 Disease management

The primary goal in the management of patients with stuttering priapism is the prevention of future episodes, which can usually be achieved pharmacologically. The management of each acute episode is similar to that for ischaemic priapism; aspiration/irrigation in combination with intracavernous injections of α -adrenergic agonists. Unfortunately, the efficacy and safety of the various treatment modalities reported in the medical literature are poorly characterised. Specifically, most reports are from small case series and the Panel is not aware of any published, well-designed, controlled studies on the efficacy and safety of these treatments [503, 532, 603].

3.4.3.4.1 α -adrenergic agonists

Studies of oral α -adrenergic agonists have suggested some benefit for daily dosing of these agents as effective prevention [605]. Side-effects include tachycardia and palpitations. Pseudoephedrine, widely used as an oral decongestant, can also be used as a first-line treatment [529]. However, its effect on corporal smooth muscle is not fully understood. Etilephrine has been used successfully to prevent stuttering priapism due to sickle cell anaemia. It is taken orally at doses of 50-100 mg daily, with response rates of up to 72% [11, 606, 607]. In one randomised, placebo-controlled, clinical study looking at medical prophylaxis with etilephrine and ephedrine, there was no difference in efficacy between the two drugs.

3.4.3.4.2 Hormonal manipulations of circulating testosterone

The aim of hormonal manipulation is to down-regulate circulating testosterone levels to suppress the action of androgens on penile erection [503, 532, 608]. This can be done through the use of GnRH agonists or antagonists, antiandrogens or oestrogens [609] (LE: 4). Potential side-effects may include hot flushes, gynaecomastia, impaired erectile function, loss of libido and asthenia. All approaches have a similar efficacy profile (LE: 4) while the potential cardiovascular toxicity of oestrogens limits their clinical use. Alternative endocrine approaches that have been used with some success include $5-\alpha$ -reductase inhibitors [610] (LE: 3) and ketoconazole, an antifungal agent that reduces adrenal and testicular androgen production [608, 611] (LE: 4).

Of the hormonal agents suggested for preventing priapism, GnRH agonists and anti-androgens appear to be the most efficacious and safe. They are recommended as primary treatments for the management of stuttering priapism in adult men (LE: 4).

The duration of hormonal treatment for effective suppression of recurrent priapic events is problematic. It is not possible to make any conclusions on the efficacy, dose and the duration of treatment. Moreover, hormonal agents have a contraceptive effect and interfere with normal sexual maturation. Caution is therefore strongly advised when prescribing hormonal treatments to pre-pubertal boys, adolescents or men who are trying with their female partner to conceive. Castrate levels of testosterone, which have a contraceptive effect, interfere with growth, and significantly affect sexual function.

3.4.3.4.3 Digoxin

Digoxin (a cardiac glycoside and a positive inotrope) is used to treat patients with congestive heart failure. Digoxin regulates smooth muscle tone through a number of different pathways leading to penile detumescence [503, 532, 612]. The use of maintenance digoxin doses (0.25-0.5 mg daily) in idiopathic stuttering priapism has been proven to reduce the number of hospital visits and to improve QoL [532]. A small, clinical, double-blind, placebo-controlled study, using digoxin, produced a decrease in sexual desire and excitement with a concomitant reduction in penile rigidity, regardless of any significant change in plasma levels of testosterone, oestrogens and luteinising hormone [612] (LE: 2b). Side-effects may include a decreased libido, anorexia, nausea, vomiting, confusion, blurred vision, headache, gynaecomastia, rash and arrhythmia.

3.4.3.4.4 Terbutaline

Terbutaline is a β -agonist that causes vasodilation, resulting in smooth muscle relaxation of the vasculature [503, 532] and has been used to prevent stuttering priapism with detumescence rates of 36% in patients with alprostadil-induced priapism [529] (LE: 3). The only randomised, placebo-controlled study (n = 68) in patients with pharmacologically-induced priapism, showed detumescence in 42% of the terbutaline-treated group compared to only 15% in the placebo-treated group [530] (LE: 1b). Side-effects include nervousness, shakiness, drowsiness, heart palpitations, headache, dizziness, hot flashes, nausea and weakness.

3.4.3.4.5 Gabapentin

Gabapentin has anticonvulsant, antinociceptive and anxiolytic properties and is widely used as an analgesic and antiepileptic agent. Its proposed mechanism of action is to inhibit voltage-gated calcium channels, which attenuates synaptic transmission [608], and reduces testosterone- and FSH levels [613]. It is given at a dose of 400 mg, four times a day, up to 2,400 mg daily, until complete penile detumescence occurs, with subsequent maintenance administration of gabapentin, 300 mg daily [614] (LE: 4). Side-effects include anorgasmia and impaired erectile function.

3.4.3.4.6 Baclofen

Baclofen is a gamma-aminobutyric acid (GABA) derivative that acts as a muscle relaxant and anti-muscle spasm agent. It can inhibit penile erection and ejaculation through GABA activity and prevents recurrent reflexogenic erections or prolonged erections from neurological diseases [503]. Oral baclofen has little efficacy and it is not usually used in stuttering priapism but intrathecal baclofen dosing is more effective [532, 615-617] (LE: 4). Side-effects include drowsiness, confusion, dizziness, weakness, fatigue, headache, hypotension and nausea.

3.4.3.4.7 Hydroxyurea

Hydroxyurea blocks the synthesis of deoxyribonucleic acid (DNA) by inhibiting ribonucleotide reductase, which has the effect of arresting cells in the S-phase [608, 618]. It is an established treatment for ameliorating sickle cell disease and improving patient life expectancy [531, 619]. For such patients with recurrent priapism there is limited evidence to suggest a medical prophylactic role (LE: 3), [608, 618, 620]. Side-effects include oligozoospermia and leg ulcers.

3.4.3.4.8 Phosphodiesterase type 5 inhibitors

Low doses of PDE5Is have a paradoxical effect in alleviating and preventing stuttering priapism, mainly in patients with idiopathic and sickle cell disease-associated priapism [503, 532, 621-625] (LE: 3). It is important to remember that therapy should be started when the penis is in its flaccid state and not during an acute episode. There is a delay of one week before treatment is effective. There are no reported impairments in male sexual function (LE: 3). Phosphodiesterase type 5 inhibitors probably act in priapism by increasing the concentration of cGMP in the smooth muscle in a NO dysfunctional state. This can occur in priapism and may result in a change in the NO pathway, with down-regulation of cavernosal PDE5 thereby preventing the complete degradation of cGMP in the corpora cavernosa [503, 532, 621, 624].

3.4.3.4.9 Intracavernosal injections

Some patients with stuttering priapism, who have been started on systemic treatments to prevent recurrence of unwanted erections, may not see therapeutic benefits immediately and may temporarily require intracavernous self-injections at home with sympathomimetic agents [503, 532]. The most commonly used drugs are phenylephrine and etilephrine (as described in the treatment of ischaemic priapism) [4, 494, 600, 607] (LE: 3). Side-effects include hypertension, coronary ischaemia and cardiac arrhythmias.

Tissue plasminogen activator (TPA) is a secreted serine protease that converts the pro-enzyme plasminogen to plasmin, which acts as a fibrinolytic enzyme. Limited clinical data have suggested that a single intracavernous injection of TPA can successfully treat patients with recalcitrant priapism [608, 626] (LE: 3). Mild bleeding is the most commonly observed side-effect.

3.4.3.4.10 Summary of evidence and recommendations for the treatment of stuttering priapism

Summary of evidence	LE
The primary goal in the management of patients with stuttering priapism is the prevention of future	
episodes, which can generally be achieved pharmacologically.	
PDE5Is have a paradoxical effect in alleviating and preventing stuttering priapism, mainly in patients	
with idiopathic and sickle cell disease associated priapism.	
The evidence with other systemic drugs (digoxin, α -adrenergic agonists, baclofen, gabapentin,	
terbutaline) is very limited.	

Recommendations	
Manage each acute episode similar to that for ischaemic priapism.	В
Use hormonal therapies (mainly gonadotropin-receptor hormone agonists or antagonists) and/or	С
antiandrogens for the prevention of future episodes in patients with frequent relapses. Do not use	
them before sexual maturation is reached.	
Initiate treatment with phosphodiesterase type 5 inhibitors (PDE5Is) only when the penis is in its flaccid	
state.	
Use digoxin, α -adrenergic agonists, baclofen, gabapentin or terbutaline only in patients with very	С
frequent and uncontrolled relapses.	
Use intracavernous self-injections at home of sympathomimetic drugs for the treatment of acute	С
episodes on an interim basis until ischaemic priapism has been alleviated.	

3.4.3.5 Follow-up

Follow-up for stuttering priapism include history and clinical examination to assess the efficacy of treatments in preventing or alleviating erectile events as well as assessing erectile function and penile fibrosis.

1. INTRODUCTION

1.1 Aim

The European Association of Urology (EAU) Guidelines Panel on Male Infertility has prepared these Guidelines to assist urologists and healthcare professionals from related specialties in the treatment of male infertility. Urologists are usually the initial specialty responsible for assessing men when male infertility is suspected. However, infertility can be a multifactorial condition requiring multidisciplinary involvement.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not and should not purport to be a legal standard of care.

1.2 Publication history

The EAU Male Infertility Guidelines were first published in 2001, followed by full-text updates in 2004, 2007, 2010, 2013, 2014 and 2015. In 2016 a scoping search was performed, covering all areas of the guideline and it was updated accordingly.

1.3 Available Publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the Male Infertility Guidelines. These are abridged versions which may require consultation together with the full text versions. The Male Infertility Panel published a number of scientific publications in the EAU journal European Urology [1-3]. A separate scientific paper on Vasectomy was published in 2012 [2]. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/male-infertility/.

1.4 Panel composition

The Male Infertility Guidelines Panel consists of urologists, endocrinologists and gynaecologists with special training in andrology and experience in the diagnosis and treatment of male infertility. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: <u>http://www.uroweb.org/guideline/male-infertility/</u>.

2. METHODS

2.1 Introduction

References used in this text are graded according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence [4]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://www.uroweb.org/guideline/</u>.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address. In particular, the Male Infertility Guidelines have been endorsed by the Hellenic Society of Reproductive Medicine.

The recommendations provided in these guidelines are based on a systematic literature search performed by the panel members. The controlled vocabulary of the MeSH database was used alongside a free text protocol, combining "male infertility" with the terms "diagnosis", "epidemiology", "investigations", "treatment", "spermatogenic failure", "genetic abnormalities", "obstruction", "hypogonadism", "varicocele", "cryptorchidism", "testicular cancer", "male accessory gland infection", "idiopathic", "contraception", "ejaculatory dysfunction", and "cryopreservation".

For the 2017 print a scoping search was performed, covering all areas of the guideline, starting from the last cut-off date April 2015 with a cut-off date of April 2016. Embase, Medline and the Cochrane Central Register of Controlled Trials databases were searched, with a limitation to reviews, meta-analyses or meta-analysis of randomised controlled trials. A total of 409 unique records were identified, retrieved and screened for relevance, of which nine publications were selected for inclusion. A detailed search strategy is available online: http://www.uroweb.org/guideline/male-infertility/.

2.2 Review

This document was subject to peer review prior to publication in 2015.

2.3 Future goals

The results of ongoing and new systematic reviews will be included in the 2018 update of the Male Infertility Guidelines. Ongoing systematic reviews include:

• What are the benefits of nutritional and/or medical therapy on the pregnancy rate and semen parameters and harms in males with idiopathic infertility? [5].

3. EPIDEMIOLOGY AND AETIOLOGY – GENERAL PRINCIPLES

3.1 Introduction

Definition

"Infertility is the inability of a sexually active, non-contracepting couple to achieve spontaneous pregnancy in one year", World Health Organization (WHO) [6].

About 15% of couples do not achieve pregnancy within one year and seek medical treatment for infertility. One in eight couples encounter problems when attempting to conceive a first child and one in six when attempting to conceive a subsequent child. Three percent of women remain involuntarily childless, while 6% of parous women are not able to have as many children as they would wish [7]. Infertility affects both men and women. In 50% of voluntarily childless couples, a male-infertility-associated factor is found together with with abnormal semen parameters. A fertile partner may compensate for the fertility problem of the man and thus infertility usually manifests if both partners have reduced fertility [6]. Male fertility can be reduced as a result of [6]:

- congenital or acquired urogenital abnormalities;
- malignancies;
- urogenital tract infections;
- increased scrotal temperature (e.g. as a consequence of varicocele);
- endocrine disturbances;
- genetic abnormalities;
- immunological factors.

In 30-40% of cases, no male-infertility-associated factor is found (idiopathic male infertility). These men present with no previous history of diseases affecting fertility and have normal findings on physical examination and endocrine, genetic and biochemical laboratory testing. However, semen analysis might reveal pathological findings in the spermiogram (see 4.2.1). Table 1 summarises the main male-infertility-associated factors. Idiopathic male infertility is assumed to be caused by several factors, including endocrine disruption as a result of environmental pollution, reactive oxygen species, or genetic and epigenetic abnormalities.

Table 1: Male infertility causes and associated factors and percentage of distribution in 10,469 patients [8]

Diagnosis	Unselected patients (n = 12,945)	Azoospermic patients (n = 1,446)
All	100%	11.2%
Infertility of known (possible) cause	42.6%	42.6%
Maldescended testes	8.4	17.2
Varicocele	14.8	10.9
Sperm autoantibodies	3.9	-
Testicular tumour	1.2	2.8
Others	5.0	1.2
Idiopathic infertility	30.0	13.3
Hypogonadism	10.1	16.4
Klinefelter's syndrome (47, XXY)	2.6	13.7
XX male	0.1	0.6
Primary hypogonadism of unknown cause	2.3	0.8
Secondary (hypogonadotropic) hypogonadism	1.6	1.9
Kallmann syndrome	0.3	0.5
Idiopathic hypogonadotropic hypogonadism	0.4	0.4
Residual after pituitary surgery	< 0.1	0.3
Late-onset hypogonadism	2.2	-
Constitutional delay of puberty	1.4	-
Others	0.8	0.8
General/systemic disease	2.2	0.5
Cryopreservation due to malignant disease	7.8	12.5
Testicular tumour	5.0	4.3
Lymphoma	1.5	4.6
Leukaemia	0.7	2.2
Sarcoma	0.6	0.9
Disturbance of erection/ejaculation	2.4	-
Obstruction	2.2	10.3
Vasectomy	0.9	5.3
Cystic fibrosis (CBAVD)	0.5	3.
Others	0.8	1.9

CBAVD = Congenital Bilateral Absence of the Vas Deferens

3.2 Recommendations on epidemiology and aetiology

Recommendations	GR
Investigate both partners simultaneously, to categorise infertility.	С
Include the fertility status of the female partner in the diagnosis and management of male subfertility	В
because this might determine the final outcome.	
Examine all men diagnosed with fertility problems, including men with abnormal semen parameters for	С
urogenital abnormalities.	

4. PROGNOSTIC FACTORS AND DIAGNOSTIC EVALUATION - GENERAL PRINCIPLES

4.1 Prognostic factors

Prognostic factors for male infertility are:

- duration of infertility;
- primary or secondary infertility;
- results of semen analysis;
- age and fertility status of female partner.

The cumulative pregnancy rate is 27% in infertile couples with two years of follow-up and oligozoospermia as the primary cause of infertility [9]. Female age is the most important single variable influencing outcome in assisted reproduction [10]. Compared to a woman aged 25 years, the fertility potential of a woman aged 35 years is reduced to 50%, to 25% at 38 years, and less than 5% at over 40 years. In many Western countries, women postpone their first pregnancy until after their education and starting a career.

4.2 Diagnostic evaluation

4.2.1 Semen analysis

A medical history and physical examination are standard assessments in all men, including scrotal ultrasound (US) [11] and semen analysis. A comprehensive andrological examination is indicated if semen analysis shows abnormalities compared with reference values (Table 2). Important treatment decisions are based on the results of semen analysis, therefore, it is essential that the complete laboratory work-up is standardised. Ejaculate analysis has been standardised by the WHO and disseminated by publication of the WHO Laboratory Manual for the Examination and Processing of Human Semen (5th edn.) [12]. It is the consensus that modern spermatology must follow these guidelines.

Table 2: Lower reference limits (5th centiles and their 95% CIs) for semen characteristics

Parameter	Lower reference limit (range)
Semen volume (mL)	1.5 (1.4-1.7)
Total sperm number (10 ⁶ /ejaculate)	39 (33-46)
Sperm concentration (10 ⁶ /mL)	15 (12-16)
Total motility (PR + NP)	40 (38-42)
Progressive motility (PR, %)	32 (31-34)
Vitality (live spermatozoa, %)	58 (55-63)
Sperm morphology (normal forms, %)	4 (3.0-4.0)
Other consensus threshold values	
рН	> 7.2
Peroxidase-positive leukocytes (10 ⁶ /mL)	< 1.0
Optional investigations	
MAR test (motile spermatozoa with bound particles, %)	< 50
Immunobead test (motile spermatozoa with bound beads, %)	< 50
Seminal zinc (µmol/ejaculate)	> 2.4
Seminal fructose (µmol/ejaculate)	> 13
Seminal neutral glucosidase (mU/ejaculate)	< 20

Cls = confidence intervals; MAR = mixed antiglobulin reaction NP = non-progressive; PR = progressive.

4.2.1.1 Frequency of semen analysis

If the results of semen analysis are normal according to WHO criteria, one test is sufficient. If the results are abnormal in at least two tests, further andrological investigation is indicated. It is important to differentiate between the following:

- oligozoospermia: < 15 million spermatozoa/mL;
- asthenozoospermia: < 32% progressive motile spermatozoa;
- teratozoospermia: < 4% normal forms.

Often, all three anomalies occur simultaneously, which is defined as oligo-astheno-teratozoospermia (OAT) syndrome. As in azoospermia, in extreme cases of oligozoospermia (spermatozoa < 1 million/mL), there is an increased incidence of obstruction of the male genital tract and genetic abnormalities.

4.2.2 Recommendations for the diagnostic evaluation of male infertility

Recommendations	
Perform semen analyses according to the guidelines of the WHO Laboratory Manual for the	A*
Examination and Processing of Human Semen (5th edn).	
Perform further andrological assessment when semen analysis is abnormal in at least two tests.	
Adhere to the 2010 WHO Manual for the standardised investigation, diagnosis and management of the	С
infertile male for diagnosis and evaluation of male subfertility.	
*Upgraded following panel consensus.	

Upgraded following panel consensus.

CONDITIONS CAUSING MALE INFERTILITY 5.

5.1 **Primary Spermatogenic Failure**

5.1.1 Aetiology

The causes of testicular deficiency are summarised in Table 3.

Table 3: Causes of testicular deficiency

Factors	Causes
Congenital	Anorchia
	Testicular dysgenesis/cryptorchidism
	Genetic abnormalities (karyotype, Y-chromosome deletions)
Acquired	Trauma
	Testicular torsion
	Post-inflammatory forms, particularly mumps orchitis
	Exogenous factors (medications, cytotoxic or anabolic drugs, irradiation, heat)
	Systemic diseases (liver cirrhosis, renal failure)
	Testicular tumour
	Varicocele
	Surgery that may compromise vascularisation of the testes and lead to testicular atrophy
Idiopathic	Unknown aetiology
	Unknown pathogenesis

5.1.2 **Diagnostic evaluation**

Routine investigations include semen analysis and hormonal determinations. Other investigations may be required depending on the individual situation.

Typical findings from the history and physical examination of a patient with testicular deficiency are:

- cryptorchidism (uni-or bilateral);
- testicular torsion and trauma; •
- genitourinary infection;
- exposure to environmental toxins;
- gonadotoxic medication (anabolic drugs, SSRIs, etc);
- exposure to radiation or cytotoxic agents;
- testicular cancer;
- absence of testes;
- abnormal secondary sexual characteristics;
- gynaecomastia;
- abnormal testicular volume and/or consistency; and
- varicocele.

5.1.2.1 Semen analysis

In non-obstructive azoospermia (NOA), semen analysis shows normal ejaculate volume and azoospermia after centrifugation. A recommended method is semen centrifugation at 3000 g for fifteen minutes and a thorough microscopic examination by phase contrast optics at ×200 magnification of the pellet. All samples can be stained and re-examined microscopically [12].

5.1.2.2 Hormonal determinations

In men with testicular deficiency, Hypergonadotropic hypogonadism is usually present, with high levels of follicle-stimulating hormone (FSH) and luteinising hormone (LH), and sometimes low levels of testosterone. Generally, the levels of FSH correlate with the number of spermatogonia: when spermatogonia are absent or markedly diminished, FSH values are usually elevated; when the number of spermatogonia is normal, but maturation arrest exists at the spermatocyte or spermatid level, FSH values are within the normal range. However, for an individual patient, FSH levels do not accurately predict the spermatogenesis status because men with maturation arrest histology could have normal FSH and testis volume and still be azoospermic [13, 14].

5.1.2.3 Ultrasonography

In addition to physical examination, a scrotal US may be helpful in finding signs of obstruction (e.g., dilatation of rete testis, enlarged epididymis with cystic lesions, or absent vas deferens) and may demonstrate signs of testicular dysgenesis (e.g., non-homogeneous testicular architecture and microcalcifications) and testis tumours. For patients with a low seminal volume and in whom distal obstruction is suspected, transrectal ultrasound (TRUS) is essential [11].

5.1.2.4 Testicular biopsy

Testicular biopsy can be part of intracytoplasmic sperm injection (ICSI) treatment in patients with clinical evidence of NOA. Testicular sperm extraction (TESE) is the technique of choice. Spermatogenesis may be focal, which means that in about 50% of men with NOA, spermatozoa can be found and used for ICSI. There is a good correlation between the histology found upon diagnostic biopsy and the likelihood of finding mature sperm cells during testicular sperm retrieval and ICSI [15-17]. However, no threshold value has been found for FSH, inhibin B, or testicular volume and successful sperm harvesting. When there are complete AZFa and AZFb microdeletions, the likelihood of sperm retrieval is virtually zero and therefore TESE procedures are contraindicated. Microsurgical TESE yields the highest sperm retrieval rates, and multiple TESE is superior to conventional TESE. Microsurgical TESE should be preferred in severe cases of non-obstructive azoospermia [18-22].

The results of ICSI are worse when using sperm retrieved from men with NOA compared to sperm from ejaculated semen and from men with obstructive azoospermia (OA) [23-27]. Birth rates are lower in NOA vs. OA (19% vs 28%) [28, 29]. ICSI results in significantly lower fertilisation and implantation rates. In longitudinal studies including patients with NOA as defined by testicular histopathology, only one out of seven NOA patients embarking for TESE and eventually ICSI will father their genetically-own child [30]. Neonatal health in terms of birth parameters, major anomalies and chromosomal aberrations in a large cohort of children born after use of non-ejaculated sperm are comparable to the outcome of children born after use of ejaculated sperm [31].

5.1.3 Summary of evidence and recommendations

Summary of evidence	LE
The WHO laboratory manual proposes reference values based on fertility therefore these reference	2a
values do not allow classification of men as infertile.	
Impaired spermatogenesis is often associated with elevated FSH concentration.	3
For patients with NOA who have spermatozoa in their testicular biopsy, intracytoplasmic sperm	2a
injection (ICSI) with fresh or cryopreserved spermatozoa is the only therapeutic option. Spermatozoa	
are found by a TESE procedure in about 50% of patients with NOA.	
Pregnancies and live births are eventually obtained in 30-50% of couples with NOA, when	3
spermatozoa have been found in the testicular biopsy.	

Recommendations	GR
For men who are candidates for sperm retrieval, give appropriate genetic counselling even when	А
testing for genetic abnormalities was negative.	
In men with non-obstructive azoospermia (NOA), perform simultaneous testicular biopsy with	А
multiple testicular sperm extraction (TESE) (or micro- TESE) to define spermatogenesis and diagnose	
intratubular germ cell neoplasma of unclassified type (ITGCNU) and eventually kryopreservation of	
sperm.	

5.2 Genetic disorders in infertility

All urologists working in andrology must have an understanding of genetic abnormalities associated with infertility, so that they can provide correct advice to couples seeking fertility treatment. Men with very low sperm counts can be offered a reasonable chance of paternity, using in vitro fertilisation (IVF), ICSI and sperm harvesting from the testes in case of azoospermia. However, the spermatozoa of infertile men show an increased rate of aneuploidy, structural chromosomal abnormalities, and DNA damage, carrying the risk of passing genetic abnormalities to the next generation. Current routine clinical practice is based on the screening of genomic DNA from peripheral blood samples, however, screening of chromosomal anomalies in spermatozoa is also feasible and can be performed in selected cases [32].

5.2.1 Chromosomal abnormalities

Chromosome abnormalities can be numerical (e.g. trisomy) or structural (e.g. inversions or translocations). In a survey of pooled data from eleven publications, including 9,766 infertile men, the incidence of chromosomal abnormalities was 5.8% [33]. Of these, sex chromosome abnormalities accounted for 4.2% and autosomal abnormalities for 1.5%. In comparison, the incidence of abnormalities was 0.38% in pooled data from three series, with a total of 94,465 newborn male infants, of which 131 (0.14%) were sex chromosome abnormalities and 232 (0.25%) autosomal abnormalities [33]. The frequency of chromosomal abnormalities increases as testicular deficiency becomes more severe. Patients with a spermatozoa count < 5 million/mL already show a 10-fold higher incidence (4%) of mainly autosomal structural abnormalities compared with the general population [34, 35]. Men with NOA are at highest risk, especially for sex chromosomal anomalies.

Based on the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis is indicated in men with azoospermia or oligozoospermia (spermatozoa < 10 million/mL) [35]. A recent study proposes to restrict karyotype to NOA men with the purpose to prevent adverse pregnancy outcomes [36]. If there is a family history of recurrent spontaneous abortions, malformations or mental retardation, karyotype analysis should be requested, regardless of the sperm concentration.

5.2.1.1 Sex chromosome abnormalities (Klinefelter's syndrome and variants [47,XXY; 46,XY/47, XXY mosaicism])

Klinefelter's syndrome is the most common sex chromosome abnormality [37]. Adult men with Klinefelter's syndrome have small firm testicles, devoid of germ cells. The phenotype varies from a normally virilised man to one with the stigmata of androgen deficiency, including female hair distribution, scant body hair, and long arms and legs due to late epiphyseal closure. Leydig cell function is commonly impaired in men with Klinefelter's syndrome [38]. Testosterone levels may be normal or low, oestradiol levels normal or elevated, and FSH levels increased. Libido is often normal despite low testosterone levels, but androgen replacement may be needed as the patient ages.

Germ cell presence and sperm production are variable in men with Klinefelter's mosaicism, 46,XY/47,XXY. Based on sperm fluorescence *in situ* hybridisation (FISH) studies showing an increased frequency of sex chromosomal abnormalities and increased incidence of autosomal aneuploidy (disomy for chromosomes 13, 18 and 21), concerns have been raised about the chromosomal normality of the embryos generated through ICSI [39].

The production of 24,XY sperm has been reported in 0.9% and 7.0% of men with Klinefelter's mosaicism [40, 41] and in 1.36-25% of men with somatic karyotype 47,XXY [42-45]. In patients with azoospermia, TESE (42%) or micro-TESE (57%) can be proposed as a therapeutic option since spermatozoa can be recovered in about 50% of cases [46]. There is growing evidence that TESE or micro TESE yields higher sperm recovery rates when done at younger age. Numerous healthy children have been born using ICSI without pre-implantation genetic diagnosis (PGD) and the conception of one 47,XXY foetus has been reported [37]. However, a study of ICSI combined with PGD in 113 embryos reported a significant fall in the rate of normal embryos for couples with Klinefelter's syndrome with respect to controls (54% vs. 77.2%) [45]. Due to the significant increase of sex chromosomal and autosomal abnormalities in the embryos of Klinefelter's patients, PGD or amniocentesis analysis should be considered.

Follow-up (possibly every year) of men with Klinefelter's syndrome is required and androgen replacement therapy should be started after fertility issues have been addressed and when testosterone level is in the range of hypoandrogenism.

TESE in peripubertal or pre-pubertal Klinefelter boys aiming at cryopreservation of testicular spermatogonial stem cells is to be considered experimental and should only be performed within a research protocol [47].

5.2.1.2 Autosomal abnormalities

Genetic counselling should be offered to all couples seeking fertility treatment (including IVF/ICSI) when the male partner has an autosomal karyotype abnormality. The most common autosomal karyotype abnormalities are Robertsonian translocations, reciprocal translocations, paracentric inversions, and marker chromosomes. It is important to look for these structural chromosomal anomalies because there is an increased associated risk of aneuploidy or unbalanced chromosomal complements in the foetus. As with Klinefelter's syndrome, sperm FISH analysis provides a more accurate risk estimation of affected offspring, however, the diffusion of this genetic test is largely limited by the availability of laboratories able to perform this analysis. When IVF/ICSI is carried out for men with translocations, PGD or amniocentesis should be performed [48, 49].

5.2.1.3 Sperm chromosomal abnormalities

Sperm can be examined for their chromosomal constitution using multicolour FISH both in men with normal karyotype and with anomalies. Aneuploidy in sperm, particularly sex chromosome aneuploidy, is associated with severe damage to spermatogenesis [33, 50-52] and with translocations [53]. Florescence *in situ* hybridisation analysis of spermatozoa is only indicated for specific andrology conditions e.g. macrocephalia [52].

5.2.2 Genetic defects

5.2.2.1 X-linked genetic disorders and male fertility

Each man has only one X-chromosome. An X-linked recessive disorder manifests in males. The defect will be transmitted to daughters, but not to sons.

5.2.2.2 Kallmann syndrome

Patients with Kallmann syndrome have hypogonadotropic hypogonadism and anosmia, but may also have other clinical features, including facial asymmetry, cleft palate, colour blindness, deafness, maldescended testes, and unilateral renal aplasia. This syndrome can be due to mutation in the Kalig-1 gene [on the X-chromosome] or in several other autosomal genes and should be tested [52, 53].

Spermatogenesis can be relatively easily induced by hormonal treatment [54], therefore, genetic screening prior to therapy is advisable although it is limited by the rarity of specialised genetic laboratories that can offer this genetic test. Treatment with gonadotropins allows natural conception in most cases, even for men with a relatively low sperm count. Thus, identification of the involved gene (X-linked, autosomal dominant or recessive) can help to provide more accurate genetic counselling, that is, risk estimation for transmission to the offspring.

5.2.2.3 Mild androgen insensitivity syndrome

The Androgen Receptor (AR) gene is located on the long arm of the X-chromosome. Mutations in the AR gene may result in mild to complete androgen insensitivity. The phenotypic features of complete androgen insensitivity syndrome are female external genitalia and absence of pubic hair (Morris syndrome). In partial androgen insensitivity syndrome, phenotypes range from predominantly female phenotype through ambiguous genitalia, to predominantly male phenotype with micropenis, perineal hypospadias, and cryptorchidism. The latter phenotype is also termed Reifenstein syndrome. In the forementioned severe forms of androgen resistance, there is no risk of transmission because affected men cannot generate their own biological children using the current technologies. Patients with mild androgen receptor causing infertility in the absence of any genital abnormality are rare, and only a few mutations have been reported in infertile [55-58] or fertile [59] men.

5.2.2.4 Other X-disorders

An unexpectedly high number of genes with a testis-specific or enriched expression pattern have

been identified on the X-chromosome, and in particular, premeiotic genes are over-represented on the X-chromosome compared with autosomal chromosomes [60]. Nevertheless, to date only a few genes have been screened in relatively small populations and none of them appear relevant for male infertility [61, 62]. On the other hand, two recent independent studies showed a significantly higher deletion load on the X-chromosome in men with spermatogenic failure with respect to normozoospermic controls [63, 64].

5.2.3 Y-chromosome and male infertility

Microdeletions on the Y-chromosome are termed AZFa, AZFb and AZFc [65]. Clinically relevant deletions remove partially, or in most cases completely, one or more of the AZF regions, and are the most frequent molecular genetic cause of severe oligozoospermia and azoospermia [66]. In each AZF region, there are several spermatogenesis candidate genes [67]. Deletions occur en bloc (i.e. removing more than one gene), thus, it is not possible to determine the role of a single AZF gene from the AZF deletion phenotype and it is unclear if they all participate in spermatogenesis. Gene-specific deletions, which remove a single gene, have been reported only in the AZFa region and concern the USP9Y gene. These studies have suggested that USP9Y is most likely to be a "fine tuner" of sperm production, and its specific screening is not advised [68].

5.2.3.1 Clinical implications of Y microdeletions

The clinical significance of Yq microdeletions can be summarised as follows:

- They are not found in normozoospermic men, proving there is a clear cut cause-and-effect relationship between Y-deletions and spermatogenic failure [69].
- The highest frequency of Y-deletions is found in azoospermic men (8-12%), followed by oligozoospermic (3-7%) men.
- Deletions are extremely rare with a sperm concentration > 5 million/mL (~0.7%).
- AZFc deletions are most common (65-70%), followed by Y-deletions of the AZFb and AZFb+c or AZFa+b+c regions (25-30%). AZFa region deletions are rare (5%).
- Complete removal of the AZFa region is associated with severe testicular phenotype (Sertoli cell only syndrome), while complete removal of the AZFb region is associated with spermatogenic rest. Complete removal of the AZFc region causes a variable phenotype ranging from azoospermia to oligozoospermia.
- Classical (complete) AZF deletions do not confer a risk for cryptorchidism or testicular cancer [66].

The specificity and genotype/phenotype correlation reported above means that Y-deletion analysis has both a diagnostic and prognostic value for testicular sperm retrieval [66].

5.2.3.1.1 Testing for Y microdeletions

Indications for AZF deletion screening are based on sperm count and include azoospermia and severe oligozoospermia (spermatozoa count < 5 million/mL). Thanks to the European Academy of Andrology (EAA) guidelines [66] and the EAA/EMQN (European Molecular Genetics Quality Network) external quality control programme (http://www.emqn.org/emqn/), Yq testing has become more reliable in different routine genetic laboratories. The EAA guidelines provide a set of primers capable of detecting > 95% of clinically relevant deletions [70].

5.2.3.1.2 Genetic counselling for AZF deletions

After conception, any Y-deletions are transmitted obligatorily to the male offspring, and genetic counselling is therefore mandatory. In most cases, father and son have the same microdeletion [70], but occasionally the son has a larger one [71]. The extent of spermatogenic failure (still in the range of azoo-/oligozoospermia) cannot be predicted entirely in the son, due to the different genetic background and the presence or absence of environmental factors with potential toxicity for reproductive function. A significant proportion of spermatozoa from men with complete AZFc deletion are nullisomic for sex chromosomes [72, 73], indicating a potential risk for any offspring to develop 45,X0 Turner's syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia [74]. Despite this theoretical risk, babies born from fathers affected by Yq microdeletions are phenotypically normal [66, 70]. This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortion of embryos bearing a 45,X0 karyotype. When ICSI is used in the presence of a Y microdeletion, long-term follow-up of any male children is needed with respect to their fertility status, and cryopreservation of spermatozoa at a young age can be considered.

5.2.3.1.3 Y-chromosome: 'gr/gr' deletion

A new type of Yq deletion, known as the gr/gr deletion, has been described in the AZFc region [75]. This deletion removes half of the gene content of the AZFc region, affecting the dosage of multicopy genes mapping inside this region. This type of deletion confers a 2.5-8 fold increased risk for oligozoospermia [70, 76-78]. The frequency of gr/gr deletion in oligozoospermic patients is ~4%.

According to four meta-analyses, gr/gr deletion is a significant risk factor for impaired sperm production [77, 78]. It is worth noting that both the frequency of gr/gr deletion and its phenotypic expression vary between different ethnic groups, depending on the Y-chromosome background. For example, in some Y haplogroups, the deletion is fixed and appears to have no negative effect on spermatogenesis. Consequently, the routine screening for gr/gr deletion is still a debated issue, especially in those laboratories serving diverse ethnic

and geographic populations. A large multicentre study has shown that gr/gr deletion is a potential risk factor for testicular germ cell tumours [79]. However, these data need further confirmation in an ethnically and geographically matched case-control study setting. For genetic counselling it is worth noting that partial AZFc deletions, gr/gr and b2/b3, may predispose to complete AZFc deletion in the next generation [80, 81].

5.2.3.1.4 Autosomal defects with severe phenotypic abnormalities and infertility

Several inherited disorders are associated with severe or considerable generalised abnormalities and infertility. Among them, Prader-Willy Syndrome, Bardet-Biedl Syndrome, Noonan's Syndrome, Myotonic dystrophy, dominant polycystic kidney disease, 5 α -reductase deficiency, etc. Patients with these defects will be well known to doctors, often from childhood. A fertility problem must be managed in the context of the care of the man as a whole including the couple's ability to care for a child.

5.2.4 Cystic fibrosis mutations and male infertility

Cystic fibrosis (CF) is a fatal autosomal-recessive disorder. It is the most common genetic disease of Caucasians; 4% are carriers of gene mutations involving the CF transmembrane conductance regulator (CFTR) gene located on chromosome 7p. It encodes a membrane protein that functions as an ion channel and influences the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two-thirds of the epididymis.

Congenital bilateral absence of the vas deferens (CBAVD) is associated with CFTR gene mutations and was found in ~2% of men with OA attending a clinic in Edinburgh, UK [82]. The incidence in men with OA varies between different countries. The clinical diagnosis of absent vasa is easy to miss and all men with azoospermia should be very carefully examined to exclude CBAVD, particularly those with a semen volume < 1.5 mL and pH < 7.0. Approximately 1,500 mutations are listed on the CFTR database http://www.genetsickkids.on.ca/cftr/. The most frequently found mutations are the F508, R117H and W1282X, but their frequency and the presence of other mutations largely depend on the ethnicity of the patient [83, 84]. Given the functional relevance of a DNA variant (the 5T allele) in a non-coding region of CFTR [79], it is now considered a mild CFTR mutation rather than a polymorphism and it should be analysed in each CBAVD patient. As more mutations are defined and tested for, almost all men with CBAVD will probably be found to have mutations. It is not practical to test for all known mutations, because many have a very low prevalence in a particular population. Routine testing is usually restricted to the most common mutations in a particular community through the analysis of a mutation panel. Given that this is a recessive disease if a second mutation is not found with the routine panel, a second step analysis is advised which comprises the direct sequencing of the entire gene. Men with CBAVD often have mild clinical stigmata of CF (e.g., history of chest infections). When a man has CBAVD, it is important to test also his partner for CF mutations. If the female partner is found to be a carrier of CFTR mutations, the couple must consider very carefully whether to proceed with ICSI using the male's sperm, as the risk of having a child with CF or CBAVD will be 50%, depending on the type of mutations carried by the parents. If the female partner is negative for known mutations, the risk of being a carrier of unknown mutations is ~0.4% [85].

5.2.4.1 Unilateral or bilateral absence/abnormality of the vas and renal anomalies

Unilateral absence of the vas deferens is usually associated with ipsilateral absence of the kidney and probably has a different genetic causation [86]. Consequently, in these subjects CFTR mutation screening is not indicated. Men with unilateral absence of the vas deferens are usually fertile, and the condition is most commonly encountered as an incidental finding in the vasectomy clinic. CFTR gene mutation screening is indicated in men with unilateral absence of the vas deferens with normal kidneys. An abdominal ultrasound should be undertaken both in unilateral and bilateral absence of vas deferens. Findings may range from unilateral absence of the vas deferens with ipsilateral absence of the kidney, to bilateral vessel and renal abnormalities, such as pelvic kidney [87].

5.2.4.2 Unknown genetic disorders

Considering the predicted high number of genes involved in male gametogenesis, it is likely that most idiopathic forms of spermatogenic disturbances are caused by mutations or polymorphisms in spermatogenesis candidate genes [61]. However, despite an intensive search for new genetic factors, no clinically relevant gene mutations or polymorphisms (except those related to the Y-chromosome) have so far been identified [61, 85, 88]. The introduction of new analytical approaches has provided evidence for the importance of Copy Number Variations (CNVs) [63, 64] and further advances are expected with Next Generation Sequencing. Intracytoplasmic sperm injection is used to enable men with severely damaged spermatogenesis to father children in situations formerly considered hopeless and where very few spermatozoa can be obtained. This has led to concern that children may be born with a foetal abnormality, because ICSI may enable defective sperm to bypass the selective processes of the female genital tract and egg covering.
Intracytoplasmic sperm injection babies have a higher risk of de novo sex chromosomal aberrations (about a threefold increase compared with natural conceptions) and paternally inherited structural abnormalities. Treatment with assisted reproductive technology was associated with increased risk of cardiovascular, musculoskeletal, urogenital, and gastrointestinal defects and cerebral palsy [89-91].

5.2.4.3 DNA fragmentation in spermatozoa

There is increased DNA damage in spermatozoa from men with oligozoospermia. This increase is associated with reduced chances of natural conception and an increased chance of early pregnancy loss [92].

5.2.4.4 Genetic counselling and ICSI

Initially, the couple should be given full information about the risks to the child in order to help them decide whether to proceed with ICSI. Where there is conflict between the wishes of the couple and the interests of the future child, it may be ethically correct to withhold therapy. When both partners are known to carry defects (e.g., CFTR mutations), there is up to a 50% chance of the child developing a clinical condition. Many clinicians and infertility clinic personnel may consider it unethical to proceed because their duty of care to the future child and the interests of society outweigh the wishes of the individual couple. If there is a conflict that cannot be resolved by agreement, the interests of a future child probably take precedence over the interests of a couple. The couple also needs to give consideration to pre-implantation diagnosis.

5.2.5 **Summary of evidence and recommendations for genetic disorders in male infertility**

Summary of evidence	LE
In men with spermatogenic damage there is a higher prevalence of chromosome abnormalities,	1b
reaching the highest frequency in NOA men.	
AZF deletions are clear-cut causes of spermatogenic impairments with diagnostic and prognostic	1a
value for TESE.	
AZF deletions will be transmitted to the son.	1a
gr/gr deletion has been confirmed as a significant risk factor for impaired sperm production, whereas	2b
further evidence of the prognostic significance of gr/gr and development of a testicular germ cell	
tumour is needed.	

Recommendations	GR
Obtain standard karyotype analysis in all men with damaged spermatogenesis (spermatozoa	В
< 10 million/mL) who are seeking fertility treatment by in vitro fertilisation (IVF).	
Provide genetic counselling in all couples with a genetic abnormality found in clinical or genetic	А
investigation and in patients who carry a (potential) inheritable disease.	
For all men with Klinefelter's syndrome, provide long-term endocrine follow-up and androgen	А
replacement therapy, if necessary.	
Do not test for microdeletions in men with obstructive azoospermia (OA) when intracytoplasmic sperm	А
injection (ICSI) is used because spermatogenesis should be normal.	
Inform men with Yq microdeletion and their partners who wish to proceed with intracytoplasmic sperm	А
injection (ICSI) that microdeletions will be passed to sons, but not to daughters.	
In men with structural abnormalities of the vas deferens (unilateral or bilateral absence), test the man	Α
and his partner for cystic fibrosis transmembrane conductance regulator (CETB) gene mutations.	

5.3 Obstructive azoospermia

Obstructive azoospermia (OA) is the absence of spermatozoa and spermatogenetic cells in semen and post-ejaculate urine due to obstruction. OA is less common than NOA and occurs in 15-20% of men with azoospermia. Men with OA present with normal FSH, normal size testes, and epididymal enlargement. Sometimes, the vas deferens is absent (CBAVD or Congenital Unilateral Absence of the Vas Deferens (CUAVD)). Obstruction in primary infertile men is frequently present at the epididymal level.

5.3.1 Classification

5.3.1.1 Intratesticular obstruction

Intratesticular obstruction occurs in 15% of men with OA [93]. Congenital forms are less common than acquired forms (post-inflammatory or post-traumatic).

5.3.1.2 Epididymal obstruction

Epididymal obstruction is the most common cause of OA, affecting 30-67% of azoospermic men [93-97]. Congenital epididymal obstruction usually manifests as CBAVD, which is associated with at least one mutation of the CF gene in 82% of cases [96]. Congenital forms of epididymal obstruction include chronic sinopulmonary infections (Young's syndrome) [98]. Acquired forms secondary to acute (e.g., gonococcal) and subclinical (e.g., chlamydial) epididymitis are most common [99, 100]. Other causes may be trauma or surgical intervention [101, 102].

5.3.1.3 Vas deferens obstruction

Vas deferens obstruction is the most common cause of acquired obstruction following vasectomy [99]. Approximately 2-6% of these men request vasectomy reversal (see Chapter 5.6). Vasal obstruction may also occur after hernia repair [103, 104]. The most common congenital vasal obstruction is CBAVD, often accompanied by CF. Unilateral agenesis or a partial defect is associated with contralateral seminal duct anomalies or renal agenesis in 80% and 26% of cases, respectively [105] (see Chapter 5.2).

5.3.1.4 Ejaculatory duct obstruction

Ejaculatory duct obstruction is found in 1-3% of cases of OA [93] and is classified as either cystic or postinflammatory. Cystic obstructions are usually congenital (i.e., Mullerian duct cyst or urogenital sinus/ejaculatory duct cysts) and are typically midline. In urogenital sinus abnormalities, one or both ejaculatory ducts empty into the cyst [106], while in Mullerian duct anomalies, the ejaculatory ducts are laterally displaced and compressed by the cyst [107]. Paramedian or lateral intraprostatic cysts are rare [108]. Post-inflammatory obstructions of the ejaculatory duct are usually secondary to urethroprostatitis [109]. Congenital or acquired complete obstructions of the ejaculatory ducts are commonly associated with low semen volume, decreased or absent seminal fructose, and acid pH. The seminal vesicles are usually dilated (anterior-posterior diameter > 15 mm) [109, 110].

5.3.1.5 Functional obstruction of the distal seminal ducts

Functional obstruction of the distal seminal ducts might be attributed to local neuropathy [111]. This abnormality is often associated with urodynamic dysfunction. Impaired sperm transport may be idiopathic or associated with selective serotonin reuptake inhibitor (SSRI) medication as well.

5.3.2 Diagnostic evaluation

5.3.2.1 Clinical history

Clinical history taking should follow the suggestions for the diagnostic evaluation of infertile men (See Chapter 4.2).

5.3.2.2 Clinical examination

Clinical examination should follow suggestions for the diagnostic evaluation of infertile men. OA is indicated by at least one testis with a volume > 15 mL, although a smaller volume may be found in some patients with:

- OA and concomitant partial testicular failure;
- enlarged and hardened epididymis;
- nodules in the epididymis or vas deferens;
- absence or partial atresia of the vas.

5.3.2.3 Semen analysis

At least two examinations must be carried out at an interval of two to three months, according to the WHO (see Chapter 4.2). Azoospermia means the inability to detect spermatozoa after centrifugation at ×400 magnification. When semen volume is low, a search must be made for spermatozoa in urine after ejaculation. Absence of spermatozoa and immature germ cells in semen smears suggest complete seminal duct obstruction.

5.3.2.4 Hormone levels

Serum FSH levels should be normal, but do not exclude a testicular cause of azoospermia. FSH level is normal in 40% of men with primary spermatogenic failure. Inhibin B seems to have a higher predictive value for normal spermatogenesis [97].

5.3.2.5 Testicular biopsy

In selected cases, testicular biopsy is indicated to exclude spermatogenic failure. Testicular biopsy should be combined with extraction of testicular spermatozoa (i.e., TESE) for cryopreservation.

5.3.3 Disease management

5.3.3.1 Intratesticular obstruction

Only TESE allows sperm retrieval in these patients and is therefore recommended.

5.3.3.2 Epididymal obstruction

Microsurgical epididymal sperm aspiration (MESA) [112] is indicated in men with CBAVD. TESE and PESA (limited cryopreservation) are also viable options [113]. Usually, one MESA procedure provides sufficient material for several ICSI cycles [114] and it produces high pregnancy and fertilisation rates [115]. In patients with azoospermia due to acquired epididymal obstruction, microsurgical reconstruction is recommended, with the preferred technique being microsurgical intussusception tubulovasostomy [116]. Anatomical recanalisation following surgery may require three to eighteen months. Before microsurgery, and in all cases where recanalisation is impossible, epididymal spermatozoa should be aspirated and cryopreserved for use in ICSI [114]. Patency rates range between 60% and 87% [102, 117] and cumulative pregnancy rates between 10% and 43%. Recanalisation success rates may be adversely affected by pre-operative and intra-operative findings.

5.3.3.3 Proximal vas deferens obstruction

Proximal vas deferens obstruction after vasectomy requires microsurgical vasectomy reversal. Vasovasostomy is also required in rare cases of proximal vasal obstructions. The absence of spermatozoa in the intra-operative vas deferens fluid suggests the presence of a secondary epididymal obstruction, especially if the seminal fluid of the proximal vas has a thick "toothpaste" appearance. Microsurgical tubulovasostomy is then indicated.

5.3.3.4 Distal vas deferens obstruction

It is usually impossible to correct large bilateral vas deferens defects, resulting from involuntary excision of the vasa deferentia during hernia surgery in early childhood or previous orchidopexy [118]. In these cases TESE/ MESA or proximal vas deferens sperm aspiration [119] can be used for cryopreservation for future ICSI.

5.3.3.5 Ejaculatory duct obstruction

The treatment of ejaculatory duct obstruction depends on its aetiology. Transurethral resection of the ejaculatory ducts (TURED) [109] can be used in large post-inflammatory obstruction and when one or both ejaculatory ducts empty into an intraprostatic midline cyst. Resection may remove part of the verumontanum. In cases of obstruction due to a midline intraprostatic cyst, incision or unroofing of the cyst is required [109]. Intra-operative transrectal US (TRUS) makes this procedure safer. If distal seminal tract evaluation is carried out at the time of the procedure, installation of methylene blue dye into the vas deferens can help to document opening of the ducts. The limited success rate of surgical treatment of ejaculatory duct obstruction in terms of spontaneous pregnancies should be weighed against sperm aspiration and ICSI. Complications following TURED include retrograde ejaculation due to bladder neck injury and urine reflux into the ejaculatory ducts, seminal vesicles, and vasa. The alternatives to TURED are MESA, TESE, proximal vas deferens sperm aspiration, seminal vesicle ultrasonically guided aspiration, and direct cyst aspiration. Spermatozoa can then be retrieved by antegrade seminal tract washout [120].

5.3.4 Summary of evidence and recommendations for obstructive azoospermia

Summary of evidence	LE
Obstructive lesions of the seminal tract are frequent in azoospermic or severely oligozoospermic	3
patients with normal-sized testes and normal reproductive hormones.	

Recommendations	GR
Perform microsurgical vasovasostomy or tubulovasostomy for azoospermia caused by vasal or	В
epididymal obstruction.	
Use sperm retrieval techniques, such as microsurgical epididymal sperm aspiration (MESA), testicular	В
sperm extraction (TESE) and percutaneous epididymal sperm aspiration (PESA) only when cryostorage	
of the material obtained is available.	

5.4 Varicocele

Varicocele is a common abnormality which may be associated with the following andrological conditions:

- Failure of ipsilateral testicular growth and development,
- Symptoms of pain and discomfort,
- Male subfertility,
- Hypogonadism.

5.4.1 Classification

The following classification of varicocele [121] is useful in clinical practice:

- Subclinical: not palpable or visible at rest or during Valsava manoeuvre, but can be shown by special tests (Doppler ultrasound studies),
- Grade 1: palpable during Valsava manoeuvre, but not otherwise,
- Grade 2: palpable at rest, but not visible,
- Grade 3: visible and palpable at rest.

5.4.2 Diagnostic evaluation

The diagnosis of varicocele is made by clinical examination and should be confirmed by US investigation and colour Duplex analysis [121]. In centres where treatment is carried out by antegrade or retrograde sclerotherapy or embolisation, diagnosis is additionally confirmed by X-ray.

5.4.3 Basic considerations

5.4.3.1 Varicocele and fertility

Varicocele is a physical abnormality present in 11.7% of adult men and in 25.4% of men with abnormal semen analysis [122]. The exact association between reduced male fertility and varicocele is unknown, but a recent meta-analysis showed that semen improvement is usually observed after surgical correction [123]. Varicocelectomy can reverse sperm DNA damage [124].

5.4.3.2 Varicocelectomy

Varicocele repair has been a subject of debate for several decades. A meta-analysis of randomised controlled trials (RCTs) and observational studies in men with only clinical varicoceles showed that surgical varicocelctomy significantly improves semen parameters in men with abnormal semen parameters including men with non-obstructive azoospermia [123, 125, 126].

In randomised controlled studies, varicocele repair in men with a subclinical varicocele was found to be ineffective in increasing the chance of spontaneous pregnancies [127]. Also, in randomised studies that included mainly men with normal semen parameters no benefit was found in favour of treatment over observation [128]. A Cochrane review from 2013 concluded that there is evidence to suggest that treatment of a varicocele in men from couples with otherwise unexplained subfertility may improve a couple's chance of pregnancy [129]. In a subgroup analyses of five RCTs comparing treatment to observation in men with a clinical varicocele, oligospermia and otherwise unexplained infertility, the analyses favoured treatment, with a combined odds ratio (OR) of 2.39 (95% CI 1.56 to 3.66) [129].

5.4.3.3 Prophylactic Varicocelectomy

In adolescents with a varicocle there is a significant risk of over-treatment since most adolescents with a varicocele will have no problem achieving pregnancy later in life [130]. Prophylactic treatment is only advised in case of documented growth deterioration of the testis as documented by serial clinical examinations and impaired semen quality.

5.4.4 Disease management

Several treatments are available for varicocele (Table 4). Current evidence indicates that microsurgical varicocelectomy is the most effective method among the different varicocelectomy techniques [130]. Microsurgical repair results in fewer complications and lower recurrence rates compared to the other techniques. This procedure, however, requires microsurgical training. The various other techniques are still considered viable options, although recurrences and hydrocele formation are more likely to occur.

Table 4: Recurrence and	complication rates	associated with	treatments for	[·] varicocele
lable in needle onee and	oomphoudon rated	accounted mini	a outilion to ron	1411000010

Treatment	Ref.	Recurrence/	Complication rates
Antegrade sclerotherapy	[131]	9	Complication rate 0.3-2.2%: testicular atrophy, scrotal haematoma, epididymitis, left-flank erythema.
Retrograde sclerotherapy	[132]	9.8	Adverse reaction to contrast medium, flank pain, persistent thrombophlebitis, vascular perforation.
Retrograde embolisation	[133, 134]	3.8-10	Pain due to thrombophlebitis, bleeding haematoma, infection, venous perforation, hydrocele, radiological complication (e.g., reaction to contrast media), misplacement or migration of coils, retroperitoneal haemorrhage, fibrosis, ureteric obstruction.
Open operation			
Scrotal operation		-	Testicular atrophy, arterial damage with risk of devascularisation and testicular gangrene, scrotal haematoma, post-operative hydrocele.
Inguinal approach	[135]	13.3	Possibility of missing out a branch of testicular vein.
High ligation	[136]	29	5-10% incidence of hydrocele (< 1%).
Microsurgical inguinal or subinguinal	[137, 138]	0.8-4	Post-operative hydrocele arterial injury, scrotal haematoma.
Laparoscopy	[139, 140]	3-7	Injury to testicular artery and lymph vessels; intestinal, vascular and nerve damage; pulmonary embolism; peritonitis; bleeding; post-operative pain in right shoulder (due to diaphragmatic stretching during pneumoperitoneum); pneumoscrotum: wound infection.

5.4.5 Summary of evidence and recommendations for varicocele

Summary of evidence	LE
The presence of varicocele in some men is associated with progressive testicular damage from	2a
adolescence onwards and a consequent reduction in fertility.	
Although the treatment of varicocele in adolescents may be effective, there is a significant risk of over-	3
treatment: the majority of boys with a varicocele will have no fertility problems later in life.	
Varicocele repair was shown to be effective in men with oligospermia, a clinical varicocele and	1a
otherwise unexplained infertility.	

Recommendations	GR
Treat varicoceles in adolescents with progressive failure of testicular development documented by	В
serial clinical examination.	
Do not treat varicoceles in infertile men who have normal semen analysis and in men with a subclinical	А
varicocele.	
Treat varicoceles in men with a clinical varicocele, oligospermia and otherwise unexplained infertility in	А
the couple.	

5.5 Hypogonadism

Hypogonadism is characterised by impaired testicular function, which may affect spermatogenesis and/or testosterone synthesis. The symptoms of hypogonadism depend on the degree of androgen deficiency and if the condition develops before or after pubertal development of the secondary sex characteristics.

5.5.1 Epidemiology and aetiology

The aetiological and pathogenetic mechanisms of male hypogonadism can be divided into three main categories:

• Primary (hypergonadotropic) hypogonadism due to testicular failure.

- Secondary (hypogonadotropic) hypogonadism caused by insufficient gonadotropin-releasing hormone (GnRH) and/or gonadotropin (FSH, LH) secretion.
- Androgen insensitivity (end-organ resistance).

The most common conditions within these three categories are given in Table 5 (see also Chapter 3.3).

Table 5: Disorders associated with male hypogonadism*

Primary (Hypergonadotropic) hypogonadism (testicular failure)*
Anorchia
Maldescended testes
Klinefelter's syndrome
Y-chromosome microdeletions
Numerical and structural chromosomal anomalies
Trauma, testicular torsion, orchitis
latrogenic (surgery, medications, irradiation, or cytostatic drugs)
Exogenous factors (toxins, heat, or occupational hazards)
Systemic diseases (liver cirrhosis, or renal failure)
Testicular tumour
Varicocele
Idiopathic (e.g., late-onset hypogonadism)
Secondary (hypogonadotropic) hypogonadism (secondary testicular failure)
Congenital
Idiopathic hypogonadotropic hypogonadism
Normosmic
Hiposmic/anosmic (Kallmann syndrome)
Acquired (tumours in the following regions)
Diencephalon (craniopharyngioma or meningioma)
Hypothalamus or pituitary
Empty sella syndrome
Granulomatous illnesses
Fractures of the skull base
Ischaemic or haemorrhagic lesions in hypothalamic area
Hyperprolactinaemia
Drugs/anabolic steroids, radiotherapy
Target organ resistance to androgens
Testicular feminisation
Reifenstein syndrome

*Modified from Nieschlag et al. [8].

5.5.2 Idiopathic hypogonadotropic hypogonadism: aetiology, diagnosis and therapeutic management

Idiopathic hypogonadotropic hypogonadism is characterised by low levels of gonadotropins and sex steroid in the absence of anatomical or functional abnormalities of the hypothalamic-pituitary-gonadal axis [141]. Idiopathic hypogonadotropic hypogonadism may be an isolated condition or may be associated with anosmia/hyposmia (Kallmann syndrome). Genetic factors causing a deficit of gonadotropins may act at the hypothalamic or pituitary level. Mutations in candidate genes (X-linked or autosomal) can be found in \sim 30% of congenital cases [141] and should be screened for prior to assisted reproduction [142]. Acquired hypogonadotropic hypogonadism can be caused by some drugs, hormones, anabolic steroids, or tumours.

A suspected tumour requires imaging [computed tomography (CT) or magnetic resonance imaging (MRI)] of the sella region and a complete endocrine work-up. Normal androgen levels and subsequent development of secondary sex characteristics (in cases of onset of hypogonadism before puberty) and a eugonadal state can be achieved by androgen replacement alone. However, stimulation of sperm production requires treatment with human chorionic gonadotropin (hCG) combined with recombinant FSH, urinary FSH or human menopausal gonadotropins (HMGs) [143]. If hypogonadotropic hypogonadism is hypothalamic in origin, an alternative to hCG treatment is pulsatile GnRH [144]. In patients who have developed hypogonadism before puberty and have not been treated with gonadotropins or GnRH, one to two years of therapy may be needed to achieve sperm production.

5.5.3 Hypergonadotropic hypogonadism: aetiology, diagnosis and therapeutic management

Many conditions in men with testicular failure are associated with hypergonadotropic hypogonadism (Table 5, see also Chapter 5.2). Most conditions listed in Table 5 only affect the reproductive function of the testes so that only the FSH level is elevated. However, it has been reported that men with infertility are at higher risk for developing impaired Leydig cell function [145], while men with Klinefelter's syndrome often show high LH values and develop hypoandrogenism with ageing [146]. A decrease in testosterone blood concentrations after extensive testicular biopsy in the context of TESE/ICSI has been observed, raising questions about the need for long-term endocrine follow-up of these patients [147]. Laboratory diagnosis of hypergonadotropic hypogonadism is based on a high level of FSH, decreased serum testosterone, and increased LH levels [142]. Testosterone levels should be evaluated in view of the serum concentration of sex hormone binding globulin (SHBG). Based on levels of total testosterone, albumin and SHBG, free and bioavailable testosterone can be calculated. Due to diurnal variation, blood samples for testosterone assessment should be taken before 10.00 am.

Generally, androgen replacement should not be given to men who are considering parenthood or in case of male infertility. Testosterone suppresses pituitary production of LH and FSH, therefore, replacement therapy should not be given for infertility. In obese men, low levels of testosterone may exist due to the conversion of testosterone to oestradiol by the enzyme aromatase [148]. Anti-oestrogens and aromatase inhibitors may help in these patients elevating FSH and LH and potentially increase sperm quality, next to weight reduction. See also EAU Guidelines on Male Hypogonadism [149].

5.5.4 Recommendations for hypogonadism

GR
А
A*
A*

*Upgraded following panel consensus.

5.6 Cryptorchidism

Cryptorchidism is the most common congenital abnormality of the male genitalia, at one year of age nearly 1% of all full-term male infants have cryptorchidism [150]. Approximately 30% of undescended testes are nonpalpable and may be located within the abdominal cavity. This guideline only deals with the management in adults.

5.6.1 Aetiology and pathophysiology

It has been postulated that cryptorchidism may be a part of the so-called testicular dysgenesis syndrome (TDS), which is a developmental disorder of the gonads caused by environmental and/or genetic influences early in pregnancy. Besides cryptorchidism, TDS includes hypospadias, reduced fertility, increased risk of malignancy, and Leydig cell dysfunction [151].

5.6.1.1 Pathophysiological effects in maldescended testes

5.6.1.1.1 Degeneration of germ cells

The degeneration of germ cells in maldescended testes is apparent after the first year of life and varies, depending on the position of the testis [152]. During the second year, the number of germ cells declines. Early treatment is therefore recommended (after the age of six months surgery should be performed within the subsequent year with age eighteen months the latest) to conserve spermatogenesis and hormone production, as well as to decrease the risk for tumours [153]. Surgical treatment is the most effective. Medical treatment with GnRH may be beneficial but long-term follow-up data are required. It has been reported that hCG treatment may be harmful to future spermatogenesis therefore, the Nordic Consensus Statement on treatment of undescended testes does not recommend it on a routine basis [154]. See also EAU Guidelines on Paediatric Urology [155].

5.6.1.1.2 Relationship with fertility

Semen parameters are often impaired in men with a history of cryptorchidism [156]. Early surgical treatment may have a positive effect on subsequent fertility [157]. In men with a history of unilateral cryptorchidism,

paternity is almost equal (89.7%) to that in men without cryptorchidism (93.7%). In men with bilateral cryptorchidism, oligozoospermia can be found in 31% and azoospermia in 42%. In cases of bilateral cryptorchidism, the rate of paternity is only 35-53% [158].

5.6.1.1.3 Germ cell tumours

As a component of the Testicular Dysgenesis Syndrome cryptorchidism is a risk factor for testicular cancer and is associated with testicular microcalcification and intratubular germ cell neoplasia of unclassified type (ITGCNU); formerly carcinoma *in situ* (CIS) of the testes. In 5-10% of testicular cancers, there is a history of cryptorchidism [159]. The risk of a germ cell tumour (GCT) is 3.6-7.4 times higher than in the general population and 2-6% of men with a history of cryptorchidism will develop a testicular tumour [150]. Orchidopexy performed before the age of puberty has been reported to decrease the risk of testicular cancer [160].

5.6.2 Disease management

5.6.2.1 Hormonal treatment

Human chorionic gonadotropin or GnRH is not recommended for the treatment of cryptorchidism in adulthood.

5.6.2.2 Surgical treatment

In adolescence removal of intra-abdominal testis (with a normal contralateral testis) can be recommended, because of the theoretical risk of later malignancy [161]. In adulthood, a palpable undescended testis should not be removed because it still produces testosterone. Furthermore, as indicated above, correction of bilateral cryptorchidism, even in adulthood, can lead to sperm production in previously azoospermic men [158]. Vascular damage is the most severe complication of orchidopexy and can cause testicular atrophy in 1-2% of cases. In men with non-palpable testes, the post-operative atrophy rate was 12% in those cases with long vascular pedicles that enabled scrotal positioning. Post-operative atrophy in staged orchidopexy has been reported in up to 40% of patients [162]. At the time of orchidopexy, performed in adulthood, testicular biopsy for detection of ITGCNU is recommended. At the time of orchiectomy in the treatment of germ cell tumours biopsy of the contralateral testis should be offered to patients at high risk for ITGCNU (i.e. history of cryptorchidism, < 12 ml. testicular volume, poor spermatogenesis [163]).

5.6.3 Summary of evidence recommendations for cryptorchidism

Summary of evidence	LE
Cryptorchidism is multifactorial in origin and can be caused by genetic factors and endocrine	2a
disruption early in pregnancy.	
Cryptorchidism is often associated with testicular dysgenesis and is a risk factor for infertility and	2b
germ cell tumours.	
Paternity in men with unilateral cryptorchidism is almost equal to that in men without cryptorchidism.	3
Bilateral cryptorchidism significantly reduces the likelihood of paternity.	3

Recommendations	GR
Do not use hormonal treatment of cryptorchidism in adults.	А
If undescended testes are corrected in adulthood, perform simultaneous testicular biopsy for	В
detection of intratubular germ cell neoplasia of unclassified type (ITGCNU) (formerly carcinoma in situ	
(CIS)).	

5.7 Idiopathic male infertility

No demonstrable cause of infertility is found in at least 44% of infertile men [164].

5.7.1 **Disease management**

5.7.1.1 Empirical treatments

A wide variety of empirical drug treatments of idiopathic male infertility have been used. However, there is little scientific evidence for an empirical approach [165]. Clomiphen citrate and tamoxifen have been widely used in idiopathic OAT: a recent meta-analysis reported some improvement in sperm quality and spontaneous pregnancy rates [166]. Androgens, bromocriptine, α -blockers, systemic corticosteroids and magnesium supplementation are not effective in the treatment of OAT syndrome. Although gonadotrophins (HMG/rFSH) might be beneficial in regards to pregnancy rates and live birth in idiopathic male factor subfertility, however, their use should be cautious given the high risk of bias and heterogeneity of available studies [167]. Men taking oral antioxidants had an associated significant increase in sperm parameters [168] and in live birth rates in IVF

patients in a Cochrane analysis [169]. Concerning natural conception the role of antioxidants needs further investigations [170].

5.7.2 Recommendation for idiopathic male infertility

Recommendations			
Medically treat male infertility only for cases of hypogonadotropic hypogonadism.	А		
No clear recommendation can be made for treatment with gonadotropins, anti-oestrogens and	В		
antioxidants even for a subset of patients.			

5.8 Male contraception

Development of male contraceptive methods is important because up to 40% of women have an unmet need for family planning, with approximately 80 million women every year having unintended or unwanted pregnancies [171]. Three of the four methods of male contraception have been in use for hundreds of years (i.e., condoms, periodic abstinence, and withdrawal). The typical first-year failure rates of traditional male methods are high (withdrawal 19%, periodic abstinence 20%, and condoms 3-14%) compared to the failure rates of 0.1-3% for modern reversible female methods [172]. For men, male contraceptive methods must be acceptable, cheap, reversible, and effective. The method nearest to being generally available clinically is hormonal male contraception, which is based on the suppression of gonadotropins and testosterone substitution to maintain male sexual function and bone mineralisation, and to prevent muscle wasting [173]. Various contraceptive regimens have been developed and tested, including testosterone monotherapy,androgen/progestin combinations, testosterone with GnRH analogues, and selective androgen-and progestinreceptor modulators [174]. There are racial differences in the response to androgens alone. However, a combination of testosterone with progestin results in complete suppression of spermatogenesis in all races, and provides contraceptive efficacy equivalent to female hormonal methods [175].

5.8.1 Vasectomy

Vasectomy is an effective method of permanent male surgical sterilisation [168]. Extensive guidelines on vasectomy were published by the EAU in 2012 [2]. Before vasectomy, the couple should be fully informed about the benefits and risks, especially as an Australian telephone survey found that 9.2% of respondents regretted having a vasectomy [176].

5.8.1.1 Surgical techniques

Various techniques are available for vasectomy. The least invasive approach is no-scalpel vasectomy which is also associated with a low rate of complications [177, 178]. The most effective occlusion technique is cauterisation of the lumen of the vas deferens and fascial interposition [179-181]. Most techniques can be carried out safely under local anaesthesia in an outpatient clinic.

5.8.1.1.1 Complications

Vasectomy does not significantly alter spermatogenesis and Leydig cell function. The volume of ejaculate remains unchanged. Potential systemic effects of vasectomy, including atherosclerosis, have not been proven, and there is no evidence of a significant increase in any systemic disease after vasectomy. An increased rate of prostate cancer in men who underwent vasectomy has not been detected [182, 183]. Acute local complications associated with vasectomy include haematoma, wound infection, and epididymitis in up to 5% of cases [182]. The potential long-term complications (e.g., chronic testicular pain) [184] must be discussed with the patient before the procedure.

5.8.1.1.2 Vasectomy failure

If an effective occlusion technique is used, the risk of recanalisation after vasectomy should be < 1% [185]. However, patients should be informed pre-operatively that, although rare, long-term recanalisation might occur [186]. No motile spermatozoa should be detected three months after vasectomy. Persistent motility is a sign of vasectomy failure, and the procedure will need to be repeated. A "special clearance" given by the urologist with non-motile spermatozoa < 100,000/mL is still under discussion [187].

5.8.2 Counselling

Counselling with regard to vasectomy must address the following aspects:

- Vasectomy should be considered irreversible,
- Vasectomy is associated with a low complication rate; however, because it is an elective operation, even small risks must be explained, because men (and their partners) might wish to consider these before giving consent,

- Vasectomy can fail, although the failure rate is low,
- Couples should be advised to continue with other effective contraception until clearance is confirmed,
- All available data indicate that vasectomy is not associated with any serious, long-term, side-effects [188],
- Vasectomy involving cauterisation and fascial interposition appears to be the most effective technique in the prevention of early recanalisation [179, 185, 189].

5.8.3 Vasectomy reversal

A wide range of surgical success rates have been published for vasectomy reversal (up to 90%), depending on the time between vasectomy and re-fertilisation, type of vasectomy (e.g., open-ended or sealed), type of reversal (vasovasostomy or vasoepididymostomy), and whether reversal was unilateral or bilateral. Microsurgical techniques should be used [190].

5.8.3.1 Length of time since vasectomy

Vasovasostomy results have shown patency rates up to 90%. The longer the interval is from vasectomy to reversal, the lower the pregnancy rate is. In a study of 1,469 men who had undergone microsurgical vasectomy reversal, patency and pregnancy rates were 97% and 76%, respectively, for an interval up to three years after vasectomy; 88% and 53% for three to eight years, 79% and 44% for nine to fourteen years, and 71% and 30% for > fifteen years [191].

5.8.3.2 Tubulovasostomy

The chance of secondary epididymal obstruction after vasectomy increases with time. After an interval of ten years, 25% of men appear to have epididymal blockage. If secondary epididymal obstruction occurs, tubulovasostomy is needed to reverse the vasectomy (see Chapter 5.3) [192].

5.8.3.3 Microsurgical vasectomy reversal vs. epididymal or testicular sperm retrieval and ICSI

According to the calculations of cost per delivery for vasectomy reversal vs. sperm retrieval/ICSI, under a wide variety of initial assumptions, it is clear that vasectomy reversal is associated with a considerably lower cost per delivery and higher delivery rates [80, 113, 193, 194]. Sperm retrieval and ICSI must yield an 81% pregnancy rate per cycle to achieve equal costs to vasectomy reversal.

5.8.4 Summary of evidence and recommendations for male contraception

Summary of evidence	LE			
Vasectomy meets best the criteria for male contribution to permanent contraception, with regard to				
efficacy, safety and side effects.				
All available data indicate that vasectomy is not associated with any serious, long-term side-effects.				
Microsurgical vasectomy reversal is a low-risk and cost-effective method of restoring fertility.	1a			
Methods of male contraception other than vasectomy are associated with high failure rates or are still				
experimental (e.g., hormonal approach).				

Recommendations	GR
Cauterisation and fascial interposition are the most effective techniques for the prevention of early	А
recanalisation.	
Inform patients seeking vasectomy about the surgical method, risk of failure, potential irreversibility,	A*
the need for post-procedure contraception until clearance, and the risk of complications.	
To achieve pregnancy, microsurgical epididymal sperm aspiration (MESA)/ percutaneous epididymal	В
sperm aspiration (PESA)/testicular sperm extraction (TESE) - together with intracytoplasmic sperm	
injection (ICSI) is a second-line option for men who decline a vasectomy reversal and those with failed	
vasectomy reversal surgery.	

*Upgraded following panel consensus

5.9 Male accessory gland infections and infertility

5.9.1 Introduction

Infections of the male urogenital tract are potentially curable causes of male infertility [121, 195, 196]. The WHO considers urethritis, prostatitis, orchitis and epididymitis to be male accessory gland infections (MAGIs) [121]. However, specific data are not available to confirm that these diseases have a negative influence on sperm quality and male fertility in general.

5.9.2 Diagnostic evaluation

5.9.2.1 Ejaculate analysis

Ejaculate analysis (see Chapter 4.2) clarifies whether the prostate is involved as part of a generalised MAGI and provides information about sperm quality. In addition, leukocyte analysis allows differentiation between inflammatory and non-inflammatory chronic pelvic pain syndrome (CP/CPPS) (NIH IIa vs. NIH 3b National Institutes of Health classification for CP/CPPS).

5.9.2.2 Microbiological findings

After exclusion of urethritis and bladder infection, $>10^6$ peroxidase-positive white blood cells (WBCs) per millilitre of ejaculate indicate an inflammatory process. In this case, a culture should be performed for common urinary tract pathogens. A concentration of $>10^3$ cfu/mL urinary tract pathogens in the ejaculate is indicative of significant bacteriospermia. The sampling time can influence the positive rate of microorganisms in semen and the frequency of isolation of different strains [197]. The ideal diagnostic test for *Chlamydia trachomatis* in semen has not yet been established [198]. In contrast to serological findings in women, antibody tests for *C. trachomatis* in seminal plasma are not indicative if no type-specific methods are used [198]. *Ureaplasma urealyticum* is pathogenic only in high concentrations ($>10^3$ cfu/mL ejaculate). No more than 10% of samples analysed for ureaplasma exceed this concentration [199]. Normal colonisation of the urethra hampers the clarification of mycoplasma-associated urogenital infections, using samples such as the ejaculate [200].

5.9.2.3 White blood cells

The clinical significance of an increased concentration of leukocytes in the ejaculate is controversial [201]. Infection is indicated only by an increased level of leukocytes. Although leukocytospermia is a sign of inflammation, it is not necessarily associated with bacterial or viral infections [202]. According to the WHO classification, leukocytospermia is defined as >10⁶ WBCs/mL. Only two studies have analysed alterations of WBCs in the ejaculate of patients with proven prostatitis [203, 204]. Both studies found more leukocytes in men with prostatitis compared to those without inflammation (CPPS, type NIH 3B).

5.9.2.4 Sperm quality

The deleterious effects of chronic prostatitis on sperm density, motility and morphology are under debate [196]. All investigations have given contradictory results, and have not confirmed that chronic prostatitis has a decisive role in altering conventional semen parameters [205-207].

5.9.2.5 Seminal plasma alterations

Seminal plasma elastase is a biochemical indicator of polymorphonuclear lymphocyte activity in the ejaculate [196, 208, 209], with a suggested cut-off level of approximately 600 ng/mL [194]. Various cytokines are involved in inflammation and can influence sperm function. Several studies have investigated the association between interleukin (IL) concentration, leukocytes, and sperm function [210-212], but no correlations have been found. The prostate is the main site of origin of IL-6 and IL-8 in the seminal plasma. Cytokines, especially IL-6, play an important role in the male accessory gland inflammatory process [213]. However, elevated cytokine levels do not depend on the number of leukocytes in expressed prostatic secretion (EPS) [214].

5.9.2.6 Glandular secretory dysfunction

Infections of the sex glands can impair their excretory function. Decreased quantities of citric acid, phosphatase, fructose, zinc, and α -glutamyl-transferase activity are indicators of disturbed prostatic secretory parameters [196]. Reduced fructose concentration indicates impaired vesicular function [199, 215].

5.9.2.7 Reactive oxygen species

Reactive oxygen species might be increased in chronic urogenital infections associated with increased leukocyte numbers [216]. However, their biological significance in prostatitis remains unclear [196].

5.9.2.8 Disease management

Treatment of chronic prostatitis is usually targeted at relieving symptoms [217, 218]. The aims of therapy for altered semen composition in male adnexitis are:

- reduction or eradication of microorganisms in prostatic secretions and semen;
- normalisation of inflammatory (e.g., leukocytes) and secretory parameters;
- improvement of sperm parameters to counteract fertility impairment [219].

Only antibiotic therapy of chronic bacterial prostatitis (NIH II according to the classification) has provided symptomatic relief, eradication of microorganisms, and a decrease in cellular and humoral inflammatory parameters in urogenital secretions. Although antibiotics might improve sperm quality [219], there is no evidence that treatment of chronic prostatitis increases the probability of conception [196, 220].

5.9.3 *Epididymitis*

Inflammation of the epididymis causes unilateral pain and swelling, usually with acute onset. Among sexually active men < 35 years of age, epididymitis is most often caused by *C. trachomatis* or *Neisseria gonorrhea* [221, 222]. Sexually transmitted epididymitis is usually accompanied by urethritis. Non-sexually transmitted epididymitis is associated with urinary tract infection and occurs more often in men aged > 35 years [223].

5.9.3.1 Diagnostic evaluation

5.9.3.1.1 Ejaculate analysis

Ejaculate analysis according to WHO criteria, might indicate persistent inflammatory activity. Transiently decreased sperm counts and forward motility are observed [221, 224, 225]. Semen culture might help to identify pathogenic microorganisms. Development of stenosis in the epididymal duct, reduction of sperm count, and azoospermia are more important in the follow-up of bilateral epididymitis (see Chapter 5.3).

5.9.3.1.2 Disease management

Antibiotic therapy is indicated before culture results are available.

Treatment of epididymitis results in:

- microbiological cure of infection;
- improvement of clinical signs and symptoms;
- prevention of potential testicular damage;
- prevention of transmission;
- decrease of potential complications (e.g., infertility or chronic pain).

Patients with epididymitis known or suspected to be caused by *N. gonorrhoeae* or *C. trachomatis* must be told to refer their sexual partners for evaluation and treatment [226].

5.9.4 Summary of evidence and recommendation for male accessory gland infections

Summary of evidence	LE
Urethritis and prostatitis are not clearly associated with male infertility.	3
Antibiotic treatment often only eradicates microorganisms; it has no positive effect on inflammatory	
alterations and cannot reverse functional deficits and anatomical dysfunction.	
Although antibiotic treatment for MAGI might provide improvement in sperm quality, it does not	
necessarily enhance the probability of conception.	

Recommendation	GR
Instruct patients with epididymitis that is known or suspected to be caused by <i>N. gonorrhoeae</i> or <i>C.</i>	В
trachomatis to refer their sexual partners for evaluation and treatment.	

5.10 Germ cell malignancy and testicular microcalcification

5.10.1 Germ cell malignancy and male infertility

Testicular germ cell tumour (TGCT) is the most common malignancy in Caucasian men aged 15-40 years, and affects approximately 1% of subfertile men. The lifetime risk of TGCT varies between ethnic groups and countries. The highest annual incidence of TGCT occurs in Caucasians, and varies from 10/100,000 (e.g., in Denmark and Norway) to 2/100,000 (e.g., in Finland and the Baltic countries). Generally, seminomas and nonseminomas are preceded by CIS, and untreated ITGCNU will eventually progress to invasive cancer [227, 228]. The most convincing evidence for a general decline in male reproductive health is the increase in testicular cancer seen in western countries [229, 230]. In almost all countries with reliable cancer registers, the incidence of testicular cancer has increased [66, 231]. Cryptorchidism and hypospadias are associated with an increased risk of testicular cancer; men with cryptorchidism and/or hypospadias are over-represented among patients with testicular cancer. Men with dysgenic testes have an increased risk of developing testicular cancer in adulthood. These cancers arise from premalignant gonocytes or CIS cells [232]. Testicular microlithiasis (TM), seen on US, can be associated with GCT and CIS of the testes.

5.10.2 Testicular germ cell cancer and reproductive function

Men with TGCT have decreased semen quality, even before cancer is diagnosed [233]. Orchidectomy implies a risk of azoospermia in these men, with sperm found in the ejaculate before the tumour-bearing testis has been removed. Semen cryopreservation before orchidectomy should therefore be considered (see Chapter 5.12).

Treatment of TGCT can result in additional impairment of semen quality [234]. In addition to spermatogenic failure, patients with TGCT have Leydig cell dysfunction, even in the contralateral testis [235]. The risk of hypogonadism may therefore be increased in men treated for TGCT. The measurement of pre-treatment levels of testosterone, SHBG, LH and oestradiol might help to anticipate post-treatment hypogonadism. Men who have had TGCT and have low normal androgen levels should receive long-term follow-up because they are at risk of developing hypogonadism as a result of an age-related decrease in testosterone production [236]. The risk of hypogonadism is most pronounced in TGCT patients treated with > three cycles of chemotherapy or irradiation of retroperitoneal lymph nodes. However, this risk is greatest at six to twelve months post-treatment. This suggests there may be some improvement in Leydig cell function, and why it is reasonable to expect initiation of androgen replacement, until the patient shows continuous signs of testosterone deficiency, even at two years follow-up [227]. The risk of low libido and erectile dysfunction is also increased in TGCT patients [237]. In case of azoospermia, testicular sperm may be recovered to safeguard patient's fertility (Onco-TESE) [238].

5.10.3 Testicular microlithiasis (TM)

Microcalcification inside the testicular parenchyma can be found in 0.6-9% of men referred for testicular US [239-241]. Although the true incidence of microcalcification in the general population is unknown, it is probably rare. However, US findings of TM are common in men with TGCT, cryptorchidism, testicular dysgenesis, infertility, testicular torsion and atrophy, Klinefelter's syndrome, hypogonadism, male pseudoherma-phroditism, varicocele, epididymal cysts, pulmonary microlithiasis, and non-Hodgkin's lymphoma. The incidence reported seems to be higher with high-frequency US machines [242]. The relationship between TM and infertility is unclear, but probably relates to dysgenesis of the testes, with degenerate cells being sloughed inside an obstructed seminiferous tubule and failure of the Sertoli cells to phagocytose the debris. Subsequently, calcification occurs. Testicular microlithiasis is found in testes at risk of malignant development. The reported incidence of TM in men with TGCT is 6-46% [243-245]. TM should therefore be considered premalignant. Testicular biopsies from men with TM have found a higher prevalence of CIS, especially in those with bilateral microlithiasis [246]. However, TM is found most often in men with a benign testicular condition and the microcalcification itself is not malignant. Further investigation of the association between TM and CIS will require testicular biopsies in large series of men without signs of TGCT. However, available data indicate that men in whom TM is found by US, and who have an increased risk of TGCT, should be offered testicular biopsy for detection of CIS. The list of high-risk patients includes men with infertility and bilateral TM, atrophic testes, undescended testes, a history of TGCT, and contralateral TM [230].

5.10.4 Recommendations for germ cell malignancy and testicular microcalcification

Re	0.00	m	ne	nd	ati	ons
ne	;CU		ne	nu	au	0115

Recommendations	GR
As for all men, encourage patients with testicular microlithiasis (TM) and without special risk factors	В
(see below) to perform self-examination because this might result in early detection of testicular germ	
cell tumour (TGCT).	
Do not perform testicular biopsy, follow-up scrotal ultrasound, routine use of biochemical tumour	В
markers, or abdominal or pelvic computed tomography (CT), in men with isolated TM without	
associated risk factors (e.g. infertility, cryptorchidism, testicular cancer, and atrophic testis).	
Perform testicular biopsy for men with TM, who belong to one of the following high-risk groups:	В
infertile and bilateral TM, atrophic testes, undescended testes, a history of TGCT.	
If there are suspicious findings on physical examination or ultrasound in patients with TM and	В
associated lesions, perform surgical exploration with testicular biopsy or orchidectomy.	
Follow men with TGCT because they are at increased risk of developing hypogonadism and sexual	В
dysfunction.	

5.11 **Disorders of ejaculation**

Disorders of ejaculation are uncommon, but important causes of male infertility.

5.11.1 Classification and aetiology

5.11.1.1 Anejaculation

Anejaculation involves complete absence of antegrade or retrograde ejaculation. It is caused by failure of semen emission from the seminal vesicles, prostate and ejaculatory ducts into the urethra [247]. True anejaculation is usually associated with a normal orgasmic sensation. True anejaculation is always associated with central or peripheral nervous system dysfunction or with drugs [248] (Table 6).

5.11.1.2 Anorgasmia

Anorgasmia is the inability to reach orgasm and can give rise to anejaculation. Anorgasmia is often a primary condition and its cause is usually psychological.

5.11.1.3 Delayed ejaculation

In delayed ejaculation, abnormal stimulation of the erect penis is needed to achieve orgasm with ejaculation [247]. Delayed ejaculation can be considered a mild form of anorgasmia. The causes of delayed ejaculation can be psychological, organic (e.g. incomplete spinal cord lesion [249] or iatrogenic penile nerve damage [250]), or pharmacological (e.g. selective serotonin re-uptake inhibitors (SSRIs), antihypertensives, or antipsychotics) [251].

5.11.1.4 Retrograde ejaculation

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation as a result of semen passing backwards through the bladder neck into the bladder. Patients experience a normal or decreased orgasmic sensation. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, urethral, or bladder neck incompetence (Table 6).

Table 6: Aetiology of anejaculation and retrograde ejaculation

Neurogenic	Pharmacological
Spinal cord injury	Antihypertensives
Cauda equina lesions	α1-adrenoceptor antagonists
Multiple sclerosis	Antipsychotics and antidepressants
Autonomic neuropathy (diabetes mellitus)	Alcohol
Retroperitoneal lymphadenectomy	
Sympathectomy or aortoiliac surgery	
Colorectal and anal surgery	
Parkinson's disease	
Urethral	Bladder neck incompetence
Ectopic ureterocele	Congenital defects/dysfunction of hemitrigone
Urethral stricture	Bladder extrophy
Urethral valves or verumontaneum hyperplasia	Bladder neck resection (transurethral resection of the
	prostate)
Congenital dopamine β -hydroxylase deficiency	Prostatectomy

5.11.1.5 Asthenic ejaculation

Asthenic ejaculation is characterised by an altered propulsive phase, with a normal emission phase [251]. The orgasmic sensation is reduced and the typically rhythmical contractions associated with ejaculation are missing. Asthenic ejaculation does not usually affect semen quality.

5.11.1.6 Premature ejaculation

The International Society for Sexual Medicine (ISSM) has adopted the first evidence-based definition of lifelong premature ejaculation (PE): "Premature ejaculation is a male sexual dysfunction characterised by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; and inability to delay ejaculation on all or nearly all vaginal penetrations; and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy". Premature ejaculation may be strictly organic (e.g., prostatitis-related) or psychogenic, partner-related or non-selective, and can be associated with erectile dysfunction. It does not impair fertility, provided intravaginal ejaculation occurs.

5.11.2 Diagnostic evaluation

Diagnostic management includes the following recommended procedures.

5.11.2.1 Clinical history

The patient must be carefully checked for diabetes, neuropathy, trauma, urogenital infection, previous surgery, and medication. Particular attention must be paid to the characteristics of micturition and ejaculation (presence of nocturnal emission, ejaculatory ability in given circumstances, and primary or acquired disorder), as well as to psychosexual aspects.

5.11.2.2 Physical examination

Genital and rectal examinations are conducted, including evaluation of the prostate, bulbocavernosus reflex and anal sphincter tone.

5.11.2.3 Post-ejaculatory urinalysis

Post-ejaculatory urinalysis of centrifuged urine can be used to determine if there is total or partial retrograde ejaculation.

5.11.2.4 Microbiological examination

Initial, mid-stream urine, expressed prostatic secretion, and/or urine after prostatic massage are cultured for evidence of prostatic infection. In cases of increased leukocytes in semen, semen culture or biochemical infection marker tests are also suggested [252].

5.11.2.5 Optional diagnostic work-up

This diagnostic work-up can include:

- neurophysiological tests (bulbocavernosus evoked response and dorsal nerve somatosensory evoked potentials);
- tests for autonomic neuropathy;
- psychosexual evaluation;
- videocystometry;
- cystoscopy;
- transrectal ultrasonography;
- uroflowmetry;
- vibratory stimulation of the penis.

5.11.3 Disease management

Infertility caused by disorders of ejaculation is seldom treated on the basis of aetiology. Treatment usually involves retrieval of spermatozoa for use in assisted reproduction techniques (ARTs). The following aspects must be considered when selecting treatment:

- age of patient and his partner;
- psychological problems of the patient and his partner;
- couple's willingness and acceptance of different fertility procedures;
- associated pathology;
- psychosexual counselling.

5.11.3.1 Aetiological treatment

If possible, any pharmacological treatment that is interfering with ejaculation should be stopped. In painful ejaculation, tamsulosin can be administered during antidepressant treatment [253]. Treatment should be given for urogenital infections (i.e., in case of painful ejaculation) [252]. Dapoxetin is an SSRI that has been introduced for the therapy of PE [254], because it appears that PE is related to serotonin levels. Psychotherapy is usually not very effective.

5.11.3.2 Symptomatic treatment

5.11.3.2.1 Premature ejaculation

Premature ejaculation can be treated with the SSRI dapoxetine or topical anaesthetic agents to increase intravaginal ejaculation latency time, behavioural therapy, and/or psychotherapy.

5.11.3.2.2 Retrograde ejaculation

In the absence of spinal cord injury, anatomical anomalies of the urethra, or pharmacological agents, drug treatment must be used to induce antegrade ejaculation (Table 7). Alternatively, the patient can be encouraged to ejaculate when his bladder is full to increase bladder neck closure [255].

Table 7: Drug therapy for retrograde ejaculation

Drug	Dosage regimen	Ref.
Ephedrine sulphate	10-15 mg four times daily	[256]
Pseudoephedrine	60 mg four times daily	[257]
Midodrine	7.5–15 mg daily	[257]
Imipramine	25 mg twice daily	[257]
Brompheniramine maleate	8 mg twice daily	[258]
Desipramine	50 mg every second day	[259]

Sperm collection from post-orgasmic urine for use in ART is recommended if:

- drug treatment is ineffective or intolerable as a result of side-effects;
- the patient has a spinal cord injury;
- drug therapy inducing retrograde ejaculation cannot be interrupted.

If the biological sperm preparation is not of sufficient quality for intrauterine insemination, the couple must undergo in vitro reproductive procedures (e.g. ICSI). In the case of insufficient drug therapy, testicular (TESE or PESA) or epididymal (MESA) sperm retrieval techniques can be used for assisted reproduction.

5.11.3.2.3 Anejaculation

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy, or psychosexual therapy for anorgasmia is not very effective. In all these cases, and in men who have a spinal cord injury, vibrostimulation (i.e., application of a vibrator to the penis) is first-line therapy. In anejaculation, vibrostimulation evokes the ejaculation reflex [260], which requires an intact lumbosacral spinal cord segment. If the quality of semen is poor, or ejaculation is retrograde, the couple may enter an IVF programme. If vibrostimulation has failed, electro-ejaculation can be the therapy of choice [261]. When electro-ejaculation fails or cannot be carried out, sperm can be retrieved from the seminal ducts by aspiration from the vas deferens [262] (see Chapter 5.3) or seminal tract washout [263]. TESE can then be used [252, 264]. Anejaculation following either surgery for testicular cancer or total mesorectal excision can be prevented using monolateral lymphadenectomy or autonomic nerve preservation [264], respectively.

5.11.4 Summary of evidence and recommendations for disorders of ejaculation

	1
Summary of evidence	LE
Ejaculation disorders can be treated using a wide range of drugs and physical stimulation (eg vibratory	3
stimulation), with a high level of efficacy.	
Pharmacotherapy includes either dapoxetine on demand (a short-acting SSRI that is the only	1a
approved pharmacological treatment for PE) or other off-label antidepressants, i.e. daily SSRIs and	
clomipramine, that are not amenable to on-demand dosing. Alternatively use topical anesthetics (LE:	
1b) or tramadol (LE: 2a).	
In men with spinal cord injury, vibrostimulation and/or electro-ejaculation are effective methods of	2
sperm retrieval.	

Recommendations	GR
Offer aetiological treatments for ejaculatory disorders before performing sperm collection and assisted	В
reproduction technique (ART).	
To treat disorders of ejaculation, offer pharmacological treatment of either dapoxetine on demand (a	A
short-acting selective serotonin reuptake inhibitors (SSRI) that is the only approved pharmacological	
treatment for premature ejaculation), or other off-label antidepressants, i.e. daily SSRIs and	
clomipramine, that are not amenable to on-demand dosing.	
Alternatively offer topical anaesthetics or tramadol.	Α

5.12 Semen cryopreservation

Cryopreservation is the storage of biological material at sub-zero temperatures [e.g., - 80 or -196°C (the boiling point of liquid nitrogen)], at which the biochemical processes of cell metabolism are slowed or interrupted. At -196°C, the biochemical reactions that lead to cell death are stopped.

5.12.1 Indications for storage

Storage of sperm is available in many clinics for the following indications:

before potentially sterilising chemotherapy or radiotherapy for cancer (onco-TESE) or for non-malignant diseases [265];

- before surgery that might interfere with fertility (e.g. bladder neck surgery in a younger man or removal of a testicle in a man with testicular malignancy, or before vasectomy or transgender surgery);
- for men with progressive decrease in semen quality as a result of diseases that have an associated risk of subsequent azoospermia (i.e., pituitary macroadenoma, craniopharyngioma, empty sella syndrome, chronic nephropathy, uncontrolled diabetes mellitus, and multiple sclerosis);
- for men with paraplegia when sperm have been obtained by electro-ejaculation or obtained by penile vibratory stimulation;
- for men with psychogenic anejaculation, after sperm have been obtained either by electro-ejaculation or a sperm retrieval procedure;
- after gonadotropin treatment has induced spermatogenesis in men with hypogonadotropic hypogonadism;
- for men with NOA, the chance of finding sperm using micro-TESE is ~50%.

Cryopreservation can be used for sperm collected through TESE, avoiding repeated sperm retrieval procedures and unnecessary hyperstimulation of the female partner:

- in any situation in which sperm have been obtained by a sperm retrieval procedure (e.g., after failed vasectomy reversal, or in some cases of epididymal obstruction not amenable to surgery);
- for storage of donor sperm, because cryopreservation reduces the risk of transmission of infection from sperm donors. According to the European directives 2004/23 EC and 2006/17 EC fresh sperm are no longer to be used for non-partner donations.

5.12.2 **Precautions and techniques**

5.12.2.1 Freezing and thawing process

The cryopreservation techniques currently used are not yet optimal because damage occurs to cells during cryopreservation and prolonged storage. Most damage occurs during freezing and thawing. Major causes of damage during freezing are ice crystal formation and cell dehydration, which disrupt the cell wall and intracellular organelles. Sperm morphology, motility and vitality decrease significantly after thawing, and cryopreservation increases the damage done to sperm DNA [266-269]. Further damage can be caused by contamination of samples with microorganisms and high levels of superoxide radicals [270, 271]. To reduce ice crystal formation, a cryopreservation solution is added before freezing. Various cryopreservation solutions are available commercially, most of which contain varying proportions of glycerol and albumin. After freezing, the samples are immersed in liquid nitrogen.

Several techniques have been developed to try to reduce damage caused by freezing and thawing, including:

- one-step freezing method [272, 273]: sample is held in the vapour phase for ten minutes before being plunged into liquid nitrogen;
- slow or multi-step method [274]: sample is gradually cooled in the vapour phase for approximately 40 minutes. A programmable automatic freezing machine, which is preset to cool at a rate of 1-10°C per minute is used.

The method available depends on the resources of the laboratory. Whichever freezing technique is used, it should be tested using donor sperm and post-thaw examination, and should regularly undergo a quality-control programme. The likelihood of sperm survival decreases with repeated freezing and thawing. The maximum viable storage time for human sperm is not known.

5.12.2.2 Cryopreservation of small numbers of sperm

Standard cryopreservation in straws is an efficient way of storing large numbers of sperm (e.g., for a donor insemination programme). However, in micro-TESE, few sperm might be obtained, and the choice is either to freeze testicular tissue and find sperm after thawing the tissue, or to freeze small numbers of sperm. If sperm are frozen in straws, it can be difficult to find any sperm after thawing. Instead, the sperm should be frozen in a pellet [275] or in a container [276].

5.12.2.3 Testing for infections and preventing cross-contamination

Sperm storage in straws is used extensively. Large numbers of straws are stored in canisters, with the straws being bathed in a pool of liquid nitrogen. Microbial contamination of the pool of liquid nitrogen results in contamination of the outside of all the straws [277]. The most widely used safeguard is to use so-called

high security closed straws. According to the European directives 2004/23 and 2006/17, samples should be tested for hepatitis B and C and human immunodeficiency virus (HIV). In case of non-partner donation, samples are also tested for *C. Trachomatis* (by Nucleic Acid Testing [NAT]) and syphilis, as well as genetics, that is, karyotype and most prevalent genetic disorders in the population to which the non-partner donor belongs. Until the test results are known, samples must be stored in an individual quarantine vessel (separate storage). If open straws are used (e.g., for vitrification purposes) some laboratories use the additional safeguard of doublewrapping the straws before freezing, although this is more costly. Some centres carry out cytomegalovirus testing and store negative and positive samples separately. Considerable ethical issues surround the storage of samples before cancer chemotherapy in men who are hepatitis-virus- or HIV-positive. Few clinics have separate storage facilities for HIV-positive samples. However, the success of antiretroviral treatment is increasing the number of HIV-positive men who may wish to store sperm. There is also concern about HIV transmission to children conceived using HIV-positive sperm, because sperm-washing techniques fail in ~5% of cases.

5.12.2.4 Fail-safe precautions to prevent loss of stored materials

Any laboratory that undertakes long-term storage of human biological materials should have procedures that guard against accidental loss of material caused by storage vessel failure. This is particularly important for sperm stored before potentially sterilising cancer chemotherapy, because these patients may not be able to obtain further sperm.

5.12.2.5 Orphan samples

In malignancy and some other situations, several years might pass before stored samples are required. Inevitably, during this time, the owners of some samples might disappear or die, leaving behind orphan samples for which the owner is no longer contactable. The duty of the laboratory and the legal ownership of these samples can create considerable problems.

5.12.3 Biological aspects

Cryopreservation induces deterioration of semen quality. After the sample has been thawed, motility [278] and morphology [279, 280] are worsened, including mitochondrial acrosomal and sperm tail damage [262]. Sperm freezing decreases motility by 31% and mitochondrial activity by 36%, and causes morphological disruption in 37% of sperm [273]. Motility is correlated best with IVF capacity of the thawed sample. Further improvement can be achieved by selecting the subpopulation of sperm with the best motility and DNA integrity and freezing these sperm in seminal plasma [275].

5.12.4 Summary of evidence and recommendations for semen cryopreservation

Summary of evidence	LE		
The purpose of sperm cryopreservation is to enable future assisted reproduction technique			
procedures.			
Cryopreservation techniques are not optimal, and future efforts are needed to improve the outcome of	3		
sperm banking.			

Recommendations	GR
Offer cryopreservation of semen to all men who are candidates for chemotherapy, radiation or surgical	А
interventions that might interfere with spermatogenesis or cause ejaculatory disorders.	
Offer simultaneous sperm cryopreservation if testicular biopsies will be performed for fertility	А
diagnosis.	
If cryopreservation is not available locally, inform patients about the possibility of visiting, or	С
transferring to a cryopreservation unit before therapy starts.	
Take precautions to prevent transmission of viral, sexually transmitted or any other infection by	С
cryostored materials from donor to recipient, and to prevent contamination of stored samples. These	
precautions include testing of the patient and the use of rapid testing and quarantine of samples until	
test results are known. Do not store samples from men who are positive for hepatitis virus or HIV in the	
same container as samples from men who have been tested and are free from infection.

1. INTRODUCTION

1.1 Aim

Androgens play a crucial role in the development and maintenance of male reproductive and sexual functions, body composition, erythropoiesis, muscle and bone health, and cognitive functions. Low levels of circulating androgens in utero can cause disturbances in male sexual development, resulting in congenital abnormalities of the male reproductive tract, such as testicular dysfunction, testicular maldescensus and hypospadias. Later in life, this may result in reduced male fertility, sexual dysfunction, decreased muscle formation and bone mineralisation, disturbances of fat metabolism and cognitive dysfunction and may contribute to the development of testicular tumours. Testosterone levels decrease slightly as a process of ageing; risks factors for developing adult onset hypogonadism are: obesity, chronic diseases and a poor general health. Symptomatic hypogonadal patients may benefit from testosterone treatment. This document presents the European Association of Urology (EAU) Guidelines on the diagnosis and treatment of male hypogonadism, with the aim to provide practical recommendations on how to deal with primary and secondary forms of hypogonadism, ageing-related decline in testosterone in men, as well as the treatment of testosterone deficiencies.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not and should not purport to be a legal standard of care.

1.2 Publication history

These Guidelines are a series of revisions of the first edition of the EAU Guidelines on Male Hypogonadism published in 2012.

1.3 Available Publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the Male Hypogonadism Guidelines. These are abridged versions which may require consultation together with the full text versions. All available material can be viewed and downloaded for personal use at the EAU website. The EAU website also includes a selection of EAU guidelines articles as well as translations produced by national urological associations: <u>http://www.uroweb.org/guidelines/online-guidelines/</u>.

1.4 Panel composition

The EAU Male Hypogonadism Panel consists of a multidisciplinary group of experts, including urologists specialising in andrology and endocrinologists.

2. METHODS

2.1 Introduction

References used in this text are assessed according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR) according to a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence [1]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://www.uroweb.org/guideline/</u>. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

The recommendations provided in these guidelines are based on a systematic literature search and review performed by the panel members in 2016. MedLine, Embase and Cochrane databases were searched to identify original articles and review articles. The controlled vocabulary of the Medical Subject Headings (MeSH) database was used alongside a 'free-text' protocol, combining 'male hypogonadism' with the terms 'diagnosis', 'epidemiology', 'investigations', 'treatment', 'testosterone', 'androgens' and 'hypogonadism'.

For the 2017 update, a scoping search was performed, covering all areas of the guideline and the search terms 'hypogonadism', 'eugonadal or hypogonadism or hypogonadal or gonadal', and 'low or lower testosterone', starting from 2011 with a cut-off date of April 2016. Embase, Medline and the Cochrane Central Register
of Controlled Trials databases were searched, with a limitation to reviews, meta-analyses or meta-analysis of randomised controlled trials. A total of 2,252 unique records were identified, retrieved and screened for relevance, of which 51 publications were selected for inclusion. A detail search strategy is available online: http://www.uroweb.org/guideline/male-hypogonadism/.

2.2 Review

This document was subject to peer review prior to publication in 2015.

2.3 Future goals

The results of ongoing and new systematic reviews will be included in the 2018 update of the Male Hypogonadism Guidelines. Ongoing systematic reviews are:-

- What are the risks of major cardiovascular events from testosterone replacement therapy (TRT)? [2].
- What are the benefits and harms of testosterone treatment for male sexual dysfunction? [3].

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Definition: male hypogonadism is a clinical syndrome caused by androgen deficiency which may adversely affect multiple organ functions and quality of life (QoL) [4]. A diagnosis of male hypogonadism must comprise both persistent clinical symptoms and biochemical evidence of testosterone deficiency.

Androgen deficiency increases slightly with age also in healthy men [5, 6]. In middle-aged men, the incidence of biochemical hypogonadism varies from 2.1-12.8% [7]. The incidence of low testosterone and symptoms of hypogonadism in men aged 40-79 varies form 2.1-5.7% [6, 7]. Hypogonadism is more prevalent in older men, in men with obesity, those with co-morbidities, and in men with a poor health status.

3.1.1 Role of testosterone for male reproductive health

Androgens, which are produced by the testis and by the adrenal glands, play a pivotal role in male reproductive and sexual function. Androgens are crucial for the development of male reproductive organs, such as the epididymis, vas deferens, seminal vesicle, prostate and penis. In addition, androgens are needed for puberty, male fertility, male sexual function, muscle formation, body composition, bone mineralisation, fat metabolism, and cognitive functions [8].

3.2 Physiology

Male sexual development starts between the 7th and 12th week of gestation. The undifferentiated gonads develop into a foetal testis through expression of multiple genes, including the sex-determining region of the Y chromosome (SRY gene complex) and the SOX genes [9]. The foetal testis produces three hormones: testosterone, insulin-like peptide 3 (INSL3) and anti-Müllerian hormone (AMH). Testosterone is needed for the stabilisation of the Wolffian ducts, resulting in formation of the epididymis, vas deferens and seminal vesicle. Anti-Müllerian hormone activity results in regression of the Müllerian ducts (Figure 1). INSL3, AMH and testosterone regulate testicular descent.

Under the influence of intratesticular testosterone, the number of gonocytes per tubule increases threefold during the foetal period [10]. In addition, testosterone is needed for development of the prostate, penis and scrotum. However, in these organs testosterone is converted into the more potent metabolite 5α -dihydrotestosterone (DHT) by the enzyme 5α -reductase. Testosterone and DHT are required for penile growth, both activating the androgen receptor [11].

Intratesticular testosterone is needed to maintain the spermatogenic process and to inhibit germ cell apoptosis [12]. The seminiferous tubules of the testes are exposed to concentrations of testosterone 25-100 times greater than circulating levels. Suppression of gonadotropins (e.g. through excessive testosterone abuse) results in a reduced number of spermatozoa in the ejaculate and hypospermatogenesis [13]. Complete inhibition of intratesticular testosterone results in full cessation of meiosis up to the level of round spermatids [14, 15]. Testosterone does not appear to act directly on the germ cells, but functions through the Sertoli cells by expression of the androgen receptor (AR) and influencing the seminiferous tubular microenvironment [15].

Testosterone can also be metabolised into oestradiol by aromatase, present in fat tissue, the prostate, the testes and bone. Oestradiol is also essential for bone mineralisation in men [16]. The production of testosterone is controlled in the foetus by placental chorion gonadotropin (hCG) and after birth by luteinising hormone (LH) from the pituitary gland. Immediately after birth, serum testosterone levels reach adult concentrations over several months (mini puberty). Thereafter and until puberty, testosterone levels are low, thus preventing male virilisation. Puberty starts with the production of gonadotropins, initiated by gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus and results in testosterone production, male sexual characteristics and spermatogenesis [17]. Figure 1 shows the development of the male reproductive system.

3.2.1 **The androgen receptor**

Testosterone exerts its action through the androgen receptor (AR), located in the cytoplasm and nucleus of target cells. During the foetal period, testosterone increases the number of ARs by increasing the number of cells with the AR and by increasing the number of ARs in each individual cell [11, 16]. The AR gene is located on the X chromosome (Xq 11-12): defects and mutations in the AR gene can result in male sexual maldevelopment, which may cause testicular feminisation or low virilisation (i.e. disorder of sexual development (DSD)). Less severe mutations in the AR gene may cause mild forms of androgen resistance and male infertility [18]. In exon 1 of the gene, the transactivation domain consists of a trinucleotide tract (cytosine-adenine-guanine (CAG) repeats) of variable length. Androgen sensitivity may be influenced by the length of the CAG repeats in exon 1 of the AR gene [18]. Shorter repeats have been associated with an increased risk for prostate disease, and longer repeats with reduced androgen action in several tissues [19]. CAG repeat number may influence androgenic phenotypical effects, even in case of normal testosterone levels [20].

Summary of evidence

Testosterone is essential for normal male development.

Figure 1: Development of the male reproductive system

FSH = follicle-stimulating hormone; LH = luteinising hormone; SRY = sex determining region of the Y chromosome; INSL3= insulin-like peptide 3.

3.3 Aetiology

Hypogonadism results from testicular failure, or is due to the disruption of one or several levels of the hypothalamic-pituitary-gonadal axis (Figure 2).

Male hypogonadism can be classified in accordance with disturbances at the level of:

- the testes (primary hypogonadism);
- the hypothalamus and pituitary (secondary hypogonadism);
- the hypothalamus/pituitary and gonads (common in adult-onset hypogonadism);
- androgen target organs (androgen insensitivity/resistance).

3.4 Classification

3.4.1 Male hypogonadism of testicular origin (primary hypogonadism)

Primary testicular failure is the most frequent cause of hypogonadism and results in low testosterone levels, impairment of spermatogenesis and elevated gonadotropins (high LH and FSH). The most common clinical forms of primary hypogonadism are Klinefelter syndrome and testicular tumours.

- Klinefelter syndrome affects 0.2% of the male population. It is the most frequent form of male hypogonadism and the most common numerical chromosomal aberration, with 47,XXY in 90% of cases [21]. It arises due to non-disjunction during paternal or maternal meiotic division of germ cells [22].
- Testicular tumours are the most frequent type of cancer in young males after puberty. Risk factors are contralateral germ cell cancer, maldescended testes, gonadal dysgenesis, infertility, testicular atrophy and familial germ cell cancer. Twenty-five per cent of men with testicular tumours develop testosterone deficiency after treatment [23-25].

The main reasons for primary hypogonadism are summarised in Table 1.

3.4.2 Male hypogonadism of hypothalamic-hypopituitary origin (secondary hypogonadism)

Central defects of the hypothalamus or pituitary cause secondary testicular failure. Identifying secondary hypogonadism is of clinical importance, as it can be a consequence of pituitary pathology (including prolactinomas) and can cause infertility, which can be restored by hormonal stimulation in most patients with secondary hypogonadism.

The most relevant forms of secondary hypogonadism are:

- Hyperprolactinemia (HP), caused by prolactin-secreting pituitary adenomas (prolactinomas) (microprolactinomas < 10 mm in diameter vs. macroprolactinomas) or drug-induced (by dopamineantagonistic effects of substances such as phenothiazine, imipramine, risperidone and metoclopramide); additional causes may be chronic renal failure or hypothyroidism. Testosterone levels may however be normal despite the presence of a prolactinoma [26].
- Isolated (formerly termed idiopathic) or congenital hypogonadotrophic hypogonadism (IHH, CHH).
- *Kallmann's syndrome* (hypogonadotrophic hypogonadism with anosmia, genetically determined, prevalence one in 10,000 males).

These disorders are characterised by disturbed hypothalamic secretion (low LH and FSH) or low levels of gonadatropin-releasing hormone (GnRH). An inborn error of migration and homing of GnRH-secreting neurons results in Kallmann's syndrome [27, 28]. The most important symptom is the constitutional delay of puberty: it is the most common cause of delayed puberty (pubertas tarda) [29]. Other rare forms of secondary hypogonadism are listed in Table 2.

3.4.3 Male hypogonadism due to mixed dysfunction of hypothalamus/pituitary and gonads (Adult-onset hypogonadism)

Combined primary and secondary testicular failure results in low testosterone levels and variable gonadotropin levels. Gonadotropin levels depend predominantly on primary or secondary failure. What has also been labelled as late-onset hypogonadism and age-related hypogonadism is comprised of these two types of hypogonadism [30-32].

3.4.4 Male hypogonadism due to defects of androgen target organs

These forms are primarily rare defects and will not be further discussed in detail in these guidelines. There are AR defects with complete, partial and minimal androgen insensitivity syndrome; Reifenstein syndrome; bulbospinal muscular atrophy (Kennedy disease); as well as 5α -reductase deficiency (for a review, see Nieschlag *et al.* 2010) [33].

The classification of hypogonadism has therapeutic implications. In patients with secondary hypogonadism, hormonal stimulation with hCG and FSH or alternatively pulsatile GnRH treatment can restore fertility in most cases [34, 35]. Detailed evaluation may, for example, detect pituitary tumours, systemic disease, or testicular tumours. Combined forms of primary and secondary hypogonadism can be observed in ageing, mostly obese men, with a concomitant age-related decline in testosterone levels resulting from defects in testicular as well as hypothalamic-pituitary function.

Table 1: Forms of primary hypogonadism

Disease	Causes of deficiency
Maldescended or ectopic testes	Failure of testicular descent, maldevelopment of the testis
Klinefelter syndrome 47,XXY	Sex-chromosomal non-disjunction in germ cells
Testicular cancer	Testicular maldevelopment
Orchitis	Viral or unspecific orchitis
Acquired anorchia	Trauma, tumour, torsion, inflammation, iatrogenic, surgical removal
Secondary testicular dysfunction	Medication, drugs, toxins, systemic diseases, varicocele
(Idiopathic) testicular atrophy/testicular dysgenesis	Male infertility (idiopathic or specific causes)
Congenital anorchia (bilateral in 1 in 20,000 males, unilateral 4 times as often)	Intrauterine torsion is the most probable cause
46,XY disorders of sexual development (DSD)	Disturbed testosterone synthesis due to enzymatic
(formerly male pseudohermaphroditism)	defects of steroid biosynthesis (17,20- hydroxlyase
	defect, 17β-hydroxysteroid dehydrogenase defect)
Gonadal dysgenesis (synonym 'streak gonads')	XY gonadal dysgenesis can be caused by mutations in different genes
46,XX male syndrome (prevalence of 1 in 10,000-	Males with presence of genetic information from the Y
20,000)	chromosome after translocation of a DNA segment of the Y to the X chromosome during paternal meiosis
Noonan syndrome (prevalence of 1 in 1,000 to 1 in 5,000)	Short stature, congenital heart diseases, cryptorchidism
Inactivating LH receptor mutations, Leydig cell	Leydig cells are unable to develop due to the
hypoplasia (prevalence of 1 in 1,000,000 to 1 in 20,000)	mutation [36]

Table 2: Forms of secondary hypogonadism

Disease	Causes of deficiency	
Hyperprolactinemia	Prolactin-secreting pituitary adenomas	
	(prolactinomas) or drug-induced	
Isolated hypogonadotropic hypogonadism (IHH)	Specific (or unknown) mutations affecting GnRH	
(formerly termed idiopathic hypogonadotrophic	synthesis or action	
hypogonadism)		
Kallmann's syndrome (hypogonadotropic	GnRH deficiency and anosmia, genetically determined	
hypogonadism with anosmia, prevalence 1 in 10,000)		
Secondary GnRH deficiency	Medication, drugs, toxins, systemic diseases	
Hypopituitarism	Radiotherapy, trauma, infections, haemochromatosis	
	and vascular insufficiency or congenital	
Pituitary adenomas	Hormone-secreting adenomas; hormone-inactive	
	pituitary adenomas; metastases to the pituitary or	
	pituitary stalk	
Prader-Willi syndrome (PWS) (formerly Prader-	Congenital disturbance of GnRH secretion	
Labhart-Willi syndrome, prevalence 1 in 10,000		
individuals)		
Congenital adrenal hypoplasia with hypogonadotropic	X-chromosomal recessive disease, in the majority of	
hypogonadism (prevalence 1 in 12,500 individuals)	patients caused by mutations in the DAX1 gene	
Pasqualini syndrome	Isolated LH deficiency	

Recommendation	LE	GR
Differentiate the two forms of hypogonadism (primary and secondary hypogonadism)	1b	В
by determining luteinising hormone and follicle-stimulating hormone levels, as this has		
implications for patient evaluation and treatment and makes it possible to identify patients with		
associated health problems and infertility.		

FSH = follicle-stimulating hormone; GnRH = Gonadotropin-releasing hormone; LH = luteinising hormone.

4. DIAGNOSTIC EVALUATION

Hypogonadism is diagnosed on the basis of persistent signs and symptoms related to androgen deficiency and assessment of consistently low testosterone levels (on at least two occasions) with a reliable method [7, 37-40]. It should be noted that over-time there is a substantial portion of men who recover from secondary hypogonadism, prompting the importance of re-evaluation if testosterone therapy has been instituted in men without defined hypothalamic or pituitary disease [41].

4.1 Clinical symptoms and laboratory testing

Low levels of circulating androgens may be associated with signs and symptoms (Table 3) [7, 42, 43]

Table 3: Clinical symptoms and signs suggestive for androgen deficiency

Clinical symptoms and signs suggestive for androgen deficiency:
Reduced testis volume
Male-factor infertility
Decreased body hair
Gynaecomastia
Decrease in lean body mass and muscle strength
Visceral obesity
Metabolic syndrome
Insulin resistance and type 2 diabetes mellitus
Decrease in bone mineral density (osteoporosis) with low trauma fractures
Mild anaemia
Sexual symptoms:
Reduced sexual desire and sexual activity
Erectile dysfunction
Fewer and diminished nocturnal erections
Cognitive and psychovegetative symptoms:
Hot flushes
Changes in mood, fatigue and anger
Sleep disturbances
Depression
Diminished cognitive function

The most prevalent symptoms of male hypogonadism in ageing men are reduced sexual desire and sexual activity, erectile dysfunction, loss of vigour and changes in mood [7, 43]. Other factors found associated with low testosterone are obesity and a poor general health status [7]. Signs and symptoms of androgen deficiency vary depending on age of onset, duration and the severity of the deficiency. Reference ranges for the lower normal level of testosterone (2.5%) have been compiled from three large community-based samples, suggesting a cut-off of 12.1 nmol/L for total serum testosterone and 243 pmol/L for free testosterone, to distinguish between normal levels and levels possibly associated with deficiency [44]. Symptoms suggesting the presence of hypogonadism [7, 43] are summarised in Table 3. It should, however, be noted that these symptoms are also found in men with normal testosterone levels and may have causes other than androgen deficiency.

In men aged 40-79 years, the threshold for total testosterone was 8 nmol/L for decreased frequency of sexual thoughts, 8.5 nmol/L for erectile dysfunction, 11 nmol/L for decreased frequency of morning erections and 13 nmol/L for diminished vigour [45, 46]. The strongest predictor for hypogonadism in this age group was three sexual symptoms (decreased sexual thoughts, weakened morning erections, erectile dysfunction) and either a total testosterone level of < 8 nmol/L or serum testosterone in the range of 8-11 nmol/L and free testosterone < 220 pmol/L. These data are based on serum samples taken in the morning, when mean levels are highest and most reproducible in younger men [47].

Laboratory testing of testosterone should reflect on the diurnal variation of testosterone. In most cases two morning (7.00 to 11.00) samples are sufficient, but should trigger further evaluation if the difference is > 20% [48]. Both immunoassay and mass spectrometry based assays can produce reliable results, as long as they are well-validated. Evaluation should be based on reference ranges for normal men provided by the laboratory measuring the samples.

In cases with discrepancy between testosterone levels and symptoms, free testosterone (FT) levels should be analysed. For determination of FT levels, the calculation of FT with the help of the sex hormone binding globulin (SHBG) is recommended.

Hypogonadism may be more subtle and not always evident by low testosterone levels. For example, men with primary testicular damage often have normal testosterone levels but high LH. This could be considered a sub-clinical or compensated form of hypogonadism. The clinical consequences of an isolated elevation of LH is not clear yet, but potentially, these men may become hypogonadal in the future.

To differentiate between primary and secondary forms of hypogonadism and to clarify hypogonadism in adult men, determination of LH serum levels is required. Both LH and testosterone serum levels should be analysed twice within 30 days, preferably in a fasting state [49].

4.2 History-taking and questionnaires

Symptoms of hypogonadism are listed in Table 3 and 4 and should be addressed during history-taking. Early onset of hypogonadism causes a lack of or minimal pubertal development, lack of development of secondary sex characteristics, possibly eunuchoid body proportions and a high-pitched voice. These signs and symptoms strongly suggest secondary hypogonadism. Adult-onset hypogonadism is characterised by sexual dysfunction, obesity and loss of vigour. Published questionnaires are unreliable, have low specificity and they are not effective for case-finding [50-53]. It is important to assess and exclude systemic illnesses, signs of malnutrition and malabsorption, as well as ongoing acute disease. Pharmacological treatments with corticosteroids, abuse of drugs such as marihuana, opiates and alcohol and previous treatment or use of testosterone and abuse of anabolic steroids should also be included in history-taking [54, 55].

4.3 Physical examination

Assessment of body mass index (BMI), the waist-hip ratio (or sagittal abdominal diameter), body hair, male pattern hair loss, presence of gynaecomastia, testicular size (measured with an orchidometer or ultrasound [US]) and examination of the penis as well as a digital rectal examination (DRE) of the prostate should be included.

4.4 Summary of evidence and recommendations for the diagnostic evaluation

Summary of evidence

The diagnosis of male hypogonadism is based on signs and symptoms of androgen deficiency, together with consistently low serum testosterone levels.

Recommendations	LE	GR
Restrict the diagnosis of testosterone deficiency to men with persistent symptoms suggesting	3	С
hypogonadism (Tables 3 and 4).		
Measure testosterone in the morning before 11.00 hours, preferably in the fasting state.	2	А
Repeat total testosterone on at least two occasions with a reliable method. In addition,	1	A
measure the free testosterone level in men with:		
- Total testosterone levels close to the lower normal range (8-12 nmol/L), to strengthen the		
laboratory assessment.		
- Suspected or known abnormal sex hormone-binding globulin (SHBG) levels.		
Assess testosterone in men with a disease or treatment in which testosterone deficiency is	2	В
common and in whom treatment may be indicated.		
This includes men with:		
- Sexual dysfunction.		
- Type 2 diabetes.		
- Metabolic syndrome.		
- Obesity.		
- Pituitary mass, following radiation involving the sellar region and other diseases in the		
hypothalamic and sellar region.		
- Treatment with medications that cause suppression of testosterone levels - e.g.		
corticosteroids and opiates.		
- Moderate to severe chronic obstructive lung disease.		
- Infertility.		
- Osteoporosis or low-trauma fractures.		
- HIV infection with sarcopenia.		
Analyse LH serum levels to differentiate between primary and secondary forms of	2	А
hypogonadism.		

4.5 Clinical consequences of hypogonadism

The clinical consequences of hypogonadism are determined by the age of onset and the severity of hypogonadism.

4.5.1 Prenatal androgen deficiency

During the first fourteen weeks of gestation, the presence of testosterone is crucial for normal virilisation of the external male genitalia. Androgen deficiency or androgen resistance due to deficient AR or LH receptor function during this stage of life may result in abnormal genital development, ranging from hypospadias to

female external genitalia with intra-abdominal testis. Frequently, patients with disorders of sexual development are diagnosed at an early age because of clearly abnormal external genitalia. However, patients at both ends of the phenotypic spectrum may go unnoticed in childhood and are diagnosed during puberty because of delayed pubertal development.

4.5.2 Prepubertal onset of androgen deficiency

At the start of puberty, rising gonadotropin levels result in increasing testicular volume and the activation of spermatogenesis and testosterone secretion. During puberty, rising testosterone levels result in the development of male secondary sex characteristics, comprising deepening of the voice, development of terminal body hair, stimulation of hair growth in sex-specific regions, facial hair, increasing penile size, increase in muscle mass and bone size and mass, growth spurt induction and eventually closing of the epiphyses.

In addition, testosterone has explicit psychosexual effects, including increased libido. Delayed puberty is defined as an absence of testicular enlargement at the age of fourteen [56]. As this is a 'statistical' definition, based on reference ranges for the onset of puberty in the normal population, delayed puberty does not necessarily indicate the presence of a disease. In cases of severe androgen deficiency, the clinical picture of prepubertal onset hypogonadism is evident (Table 4) and diagnosis and treatment are fairly straightforward. The major challenge in younger individuals with presumed isolated (congenital) hypogonadotrophic hypogonadism is to differentiate the condition from a constitutional delay in puberty and to determine when to start androgen treatment. In milder cases of androgen deficiency, as seen in patients with Klinefelter syndrome, pubertal development can be normal, incomplete or delayed, resulting in a more subtle phenotypic picture. In these patients, several clues may lead to a diagnosis of hypogonadism. These include: small testes, (a history of) cryptorchidism, gynaecomastia, sparse body hair, eunuchoid habitus, low bone mass and sub-fertility [57].

Table 4: Signs and symptoms suggesting prepubertal-onset hypogonadism

Delayed puberty
Small testes
Cryptorchidism
Gynaecomastia
High-pitched voice
Unclosed epiphyses
Linear growth into adulthood
Eunuchoid habitus
Sparse body hair/facial hair
Infertility
Low bone mass
Sarcopenia
Reduced sexual desire/activity

4.5.3 Adult-onset hypogonadism

Adult-onset hypogonadism is defined as testosterone deficiency, usually associated with clinical symptoms or signs in a person who has had normal pubertal development and, as a result, developed normal male secondary sex characteristics.

Depending on the underlying cause of hypogonadism, the decline in gonadal function may be gradual and partial. The resulting clinical picture may be variable, and the signs and symptoms may be obscured by the physiological phenotypic variation. Symptoms that have been associated with adult-onset hypogonadism are summarised in Table 3. Most of these symptoms have a multi-factorial aetiology, are reminiscent of normal ageing and can also be found in men with completely normal testosterone levels [5]. As a result, signs and symptoms of adult-onset hypogonadism may be non-specific, and confirmation of a clinical suspicion by hormonal testing is mandatory. For many of the symptoms mentioned above, the probability of their presence increases with lower plasma testosterone levels. Most studies indicate a threshold level below which the prevalence of symptoms starts to increase [43, 58]. This threshold level is near the lower level of the normal range for plasma testosterone levels in young men, but there appears to be a wide variation between individuals and, even within one individual, the threshold level may be different for different target organs. Androgen receptor activity may also contribute to this variance [59, 60].

4.5.4 Hypogonadism in Type 2 Diabetes

There is a high prevalence of hypogonadism in men with type 2 diabetes mellitus [61-63]. The commonest symptom and main indication for treatment is that of sexual dysfunction. Erectile dysfunction has been reported in up to 70% of men with diabetes but may be caused by different or combined aetiologies (vasculopathy, neuropathy, medications, psychological factors) as well as hypogonadism in approximately 30%. Testosterone therapy alone may be insufficient and a combination with PDE5 inhibitors may be necessary. Testosterone deficiency is also associated with a failure of PDE5 inhibitor therapy [64]. Randomised controlled trials of at least six months duration testosterone treatment therapy (TRT) have reported significant improvement in sexual desire, but not erectile function [65-67] in men with type 2 diabetes, although one study did not find a benefit on sexual desire [68].

Testosterone deficiency is associated with an adverse cardiovascular risk profile in men with type 2 diabetes and TRT can improve insulin resistance and glycaemic control in some studies, reduce percentage body fat, and waist circumference and lower total and LDL-cholesterol, lipoprotein (a), and a small fall in HDL-cholesterol may occur. There is some evidence that it may reduce mortality [65, 69, 70]. These benefits, however, are not currently stand alone indications for TRT in type 2 diabetes and require further research but, could be considered as potential added benefits when used in conjunction when subjects are treated for sexual dysfunction.

4.5.4.1 Recommendations for screening men with adult-onset hypogonadism

Recommendations	LE	GR
Screen for testosterone deficiency only in adult men with consistent and multiple signs and		
symptoms listed in Table 3.		
Young men with testicular dysfunction and men older than 50 years of age with low		В
testosterone should additionally be screened for osteoporosis.		

5. DISEASE MANAGEMENT

5.1 Indications and contraindications for treatment

Testosterone treatment aims to restore testosterone levels to the physiological range in men with consistently low levels of serum testosterone and associated symptoms of androgen deficiency. The aim of testosterone treatment is to restore physiological androgen dependent functions and to improve QoL, e.g. sense of wellbeing, sexual function, muscle strength and bone mineral density. Table 5 highlights the main indications for testosterone treatment. Table 6 lists the main contraindications against testosterone treatment.

Table 5: Main indications for testosterone treatment

Delayed puberty (constitutional or congenital forms (HH, Kallmann's syndrome))
Klinefelter syndrome with hypogonadism
Sexual dysfunction and low testosterone
Low bone mass in hypogonadism
Adult men with low testosterone and consistent and preferably multiple signs and symptoms of
hypogonadism following unsuccessful treatment of obesity and comorbidities (listed in Table 3)
Hypopituitarism
Testicular dysfunctions and hypogonadism
Type 2 diabetes mellitus with hypogonadism

Table 6: Contraindications against testosterone treatment

Locally advanced or metastatic prostate cancer
Male breast cancer
Men with an active desire to have children
Haematocrit > 0.54
Severe chronic cardiac failure/New York Heart Association Class IV

5.2 Benefits of treatment

In congenital hypogondotrophic hypogonadism, treatment is usually indicated. In these patients hormonal stimulation with hCG and FSH or alternatively pulsatile GnRH treatment can induce puberty, restore fertility in most cases and normalise bone mineralisation [35, 71, 72]. If active desire to have children is not the focus of treatment after puberty induction, life-long testosterone substitution is recommended [73].

In adult-onset hypogonadism testosterone treatment may improve symptoms, but many hypogonadal men are sick and/or obese, and weight reduction, lifestyle modification and good treatment of comorbidities are more important than just testosterone treatment [74a, 74b].

Testosterone treatment may present several benefits regarding body composition, metabolic control, psychological and sexual parameters. Observational trials show a correlation between restored physiological testosterone levels, muscle mass and strength measured as leg press strength and quadriceps muscle volume [42, 75-77]. Low testosterone levels are common in men with chronic renal failure on haemodialysis and there is also a worsening of prognosis associated to lower testosterone levels. There, is however, a lack of interventions studies evaluating eventual benefits of testosterone therapy in this group of men [78]. Similar positive results are shown in meta-analysis designed to address the value of the role of exogenous testosterone in bone mineral density: it is evident how testosterone therapy improves mineral density at the lumbar spine producing a reduction in bone resorption markers. Available trials failed to demonstrate a similar effect at the femoral neck. At present though, bone mineral density seems to remain a surrogate marker of bone health and there are no RCTs detailing actual bone fracture risk [76, 79-81]. Improvement in bone mineral density and bone structure in men with Klinefelter syndrome has also been reported [82]. Body composition is influenced by testosterone therapy in hypogonadal men, with a consequent decrease of fat mass and an increase in lean body mass [76, 83]. Men with hypogonadism are at an increased risk of having osteoporosis and osteopenia. Young men with testicular dysfunction and men older than 50 years of age with low testosterone should additionally be screened for osteoporosis [84].

Several studies based on testosterone undecanoate, demonstrate a significant reduction in trunk and waist fat with an evident decrease in waist size [85-87]. In the same trials, testosterone undecanoate administration showed an improvement in body weight, body mass index and lipid profile after three months of therapy [85].

A strong correlation between decreased testosterone levels and increased cardiovascular mortality has been reported in meta-analyses and retrospective studies showing that total-testosterone and free-testosterone in the normal range are related moreover to reduced all-cause mortality [88-94]. It is suggested that low testosterone is a biomarker for a poor health condition and as such is a marker for increased risk of cardiovascular disease [95]. Of interest is also the observation that testosterone treatment (transdermal) over a three year period compared to placebo did not cause any change in dynamics of atherosclerotic plaque development in the intima media of the carotids [96].

Sexual dysfunction and testosterone treatment

Sexual dysfunction symptoms are the most predictive determinant sign of potential male hypogonadism: 23 to 36% of men with sexual dysfunction are hypogonadal [97]. Testosterone therapy was shown to moderately increase sexual function in hypogonadal men [98]. In a large RCT, testosterone therapy resulted in a significant improvement of sexual arousal, interest and drive [99]. Two RCTs have reported that testosterone therapy has a benefit on sexual function in men with type 2 diabetes [65, 100]. In a recent meta-analyses of RCTs on testosterone therapy and sexual function, testosterone showed to have a positive influence on sexual function but only in clearly hypogonadal men (T < 8 nmol/L) [66]. Improvement of sexual symptoms will largely depend on the aetiology of the dysfunction: testosterone therapy in men with normal testosterone levels is not very effective, but testosterone therapy may help improve response to PDE5 inhibitors in hypogonadal men [101], although a recent meta analyses of studies with daily PDE5 inhibitors in men with normal testosterone showed that PDE5 inhibitors were equally effective in men with low testosterone as in men with normal testosterone [102]. The advantage of the use of PDE5 inhibitors for erectile dysfunction is that these drugs are usually very effective and work fast. In contrast, testosterone treatment for erectile dysfunction may take up to several months to become effective. The use of a PDE5 inhibitor may also increase serum testosterone levels [103].

In a small RCT, testosterone therapy did not improve cognitive functions but had a positive effect on verbal memory and depressive symptoms [104]. Significant improvement of depressive symptoms in men treated with testosterone undecanoate were reported in a recent randomised trial [67]. Meta-analysis of data from randomised placebo-controlled trials has shown a significant positive impact of testosterone on mood [105].

In a recent review it is highlighted that QoL and physical function appears to improve in frail men with low testosterone, when treated with testosterone [46].

Summary of evidence	LE	
Testosterone treatment may improve symptoms, but many hypogonadal men have a chronic illness		
increase testosterone and reduce associated risks for diabetes and cardiovascular diseases.		
Testosterone treatment can improve body composition, bone mineralisation, signs of the metabolic		
syndrome, male sexual problems, diabetes regulations, memory and depressive symptoms.		
A reduction in BMI and waist size, improved glycaemic control and lipid profile are observed in	2a	
hypogonadal men receiving testosterone treatment.		

Recommendations	LE	GR
Improve lifestyle, reduce weight in case of obesity and treat comorbidities before starting		С
testosterone therapy.		
In hypogonadal men with erectile dysfunction start with a PDE5-inhibitor as first line treatment		А
and add testosterone in case of a poor response to PDE5i treatment.		
Consider testosterone therapy in hypogonadal men with diabetes.		В

5.3 Choice of treatment

The aim of testosterone treatment is to restore physiological testosterone levels in hypogonadal men [106]. Several preparations are available, which differ in the route of administration, pharmacokinetics and adverse events, and the selection should be a joint decision by both the patient and the physician [107]. Short-acting preparations are preferred to long-acting depot administration in the initial treatment phase, so that any adverse events that may develop can be observed early and treatment can be discontinued if needed [108]. The available agents are oral preparations, intramuscular injections and transdermal gel and patches.

5.3.1 **Preparations**

5.3.1.1 Testosterone undecanoate

Testosterone undecanoate (TU) is the most widely used and safest oral delivery system. It rarely causes a rise in testosterone levels above the mid-range and it is therefore infrequently associated with side-effects [106]. In oral administration, resorption depends on simultaneous intake of fatty food. Testosterone undecanoate is also available as a long-acting intramuscular injection (with intervals of up to three months). This long period of action ensures a normal testosterone serum concentration for the entire period, but the relatively long wash-out period may cause problems if complications appear [109]. In the recent IPASS study, a total worldwide sample of 1,438 men was evaluated during nine to twelve months of treatment with injectable TU: TU was effective and well-tolerated, with marked improvements in several psychosexual functions and waist circumference. Adverse events and adverse drug reactions (more common: increase in hematocrit, increase in PSA, and injection site pain) were 12% and 6% respectively, mostly mild to moderate, and with no increase in prostate cancer observed [87].

5.3.1.2 Testosterone cypionate and enanthate

Testosterone cypionate and enanthate are available as short-acting intramuscular delivery systems (with intervals of 2-3 weeks) and represent safe and valid preparations. However, these preparations may cause fluctuations in serum testosterone from high levels to subnormal levels, and they are consequently associated with periods of well-being alternating with periods of unsatisfactory clinical response [110, 111]. They are also associated with increased rates of erytrocytosis.

5.3.1.3 Transdermal testosterone

Transdermal testosterone preparations are available as 1% or 2% gel. They provide a uniform and normal serum testosterone level for 24 hours (daily interval). Common side-effects are the risk of interpersonal transfer if appropriate precautions are not taken [112, 113]. The topical application of Testosterone 2% to the axillae has been demonstrated to have a safe and effective profile in a multinational open-label clinical study and has been approved in the United States and Europe [114-116]. It should be noted that patients with high BMI may require higher doses since obesity seems to affect the pharmacokinetics of transdermal testosterone preparations [117, 118].

5.3.1.4 Future perspectives

A randomised phase II clinical trial detailing the efficacy and safety of Enclomiphene Citrate (EC) as an alternative to testosterone preparations is available. Enclomiphene Citrate should provide adequate supplementation of testosterone while preventing oligospermia with a sufficient safety profile. At present it is used as an off-label medication for male hypogonadism [119-122].

5.4 Hypogonadism and fertility issues

Exogenous testosterone reduces endogenous testosterone production by negative feedback on the hypothalamic-pituitary-gonadal axis. If hypogonadism coincides with fertility issues, hCG treatment should be considered, especially in men with low gonadotropins (secondary hypogonadism). Human chorionic gonadotropin stimulates testosterone production of Leydig cells. Normal physiological serum levels can be achieved with a standard dosage of 1,500-5,000 IU administered intramuscularly or subcutaneously twice weekly. In patients with secondary hypogonadism hCG treatment is combined with FSH treatment (usually 150 IU three times weekly intramuscular or subcutaneous): to induce HCG alone may lead to suppression of FSH (negative feedback of testosterone production).

Human chorionic gonadotropin treatment has higher costs than testosterone treatment. There is insufficient information about the therapeutic and adverse effects of long-term hCG treatment. This type of treatment can therefore not be recommended for long-term treatment of male hypogonadism, except in patients in whom fertility treatment is indicated. Previous testosterone treatment does not seem to affect the efficacy of gonadotropin therapy [71, 73]. Anti-oestrogens and aromatase inhibitors are further options for hypogonadal patients with an active child wish, though evidence is limited [123].

Table 7: Testosterone preparations for replacement therapy

5.5 Recommendations for testosterone replacement therapy

Recommendations	LE	GR
Fully inform the patient about expected benefits and side-effects of the treatment option.	3	A
Select the preparation with a joint decision by an informed patient and the physician.		
Use short-acting preparations rather than long-acting depot administration when starting the	3	В
initial treatment, so that therapy can be adjusted or stopped in case of adverse side-effects.		
Do not use testosterone therapy in patients with male infertility and active child wish since it	1b	A
may suppress spermatogenensis.		
Only use human chorionic gonadotropin treatment for hypogonadotrophic hypogonadal	1b	В
patients with simultaneous fertility treatment.		
In patients with adult-onset hypogonadism, only prescribe testosterone treatment in men with	2	A
multiple symptoms and if weight loss, lifestyle modification and good treatment balance of		
comorbidities have proven unsuccessful.		

5.6 Risk factors in testosterone treatment

Physicians are often reluctant to offer testosterone treatment especially in elderly men due to the potential risk of this therapy. The most common doubts are represented by the possible consequences on the prostate and cardiovascular risks.

5.6.1 Male breast cancer

Male breast cancer is a rare disease with an incidence of less than 1% of all male cancers [126]. The incidence is higher in men with Klinefelter syndrome. Testosterone treatment is contraindicated in men with a history of breast cancer [31]. Association between testosterone treatment and development of breast cancer is not supported by strong evidence although there are some reports based on small numbers of patients [127].

5.6.2 Risk for prostate cancer

Prostate cancer growth may be influenced by testosterone: studies report that hypogonadism is associated with a lower incidence of prostate cancer, but if prostate cancer occurs in hypogonadal men it usually has an advanced stage and a higher Gleason score [128, 129]. Short-term randomised controlled trials support the hypothesis that testosterone treatment does not result in changes in prostatic histology nor in a significant increase in intraprostatic testosterone and DHT [130, 131]. Observational studies indicate that testosterone therapy does not increase the risk of developing prostate cancer or results in more aggressive prostate tumours [87, 130, 132, 133].

Testosterone treatment is clearly contraindicated in men with advanced prostate cancer. A topic under debate is the use of testosterone treatment in hypogonadal men with history of prostate cancer and no evidence of active disease. So far only studies with a limited number of patients and a relatively short period of follow-up are available and indicate no increased risk for prostate cancer recurrence [134, 135]. According to a recent retrospective study on hypogonadal men with previous history of prostate cancer receiving testosterone following cancer diagnosis, treatment was not associated with increased overall or cancer-specific mortality, but testosterone treatment was more likely to be prescribed in patients undergoing radical prostatectomy for well-differentiated tumours [136]. No randomised placebo-controlled trials are available yet to document its long-term safety in these patients [106]. Symptomatic hypogonadal men who have been surgically treated for localised prostate cancer and who are currently without evidence of active disease (i.e. measurable PSA, abnormal rectal examination, evidence of bone/visceral metastasis) can be cautiously considered for testosterone treatment [137]. In these men, treatment should be restricted to those patients with a low risk for recurrent prostate cancer (i.e. Gleason score < 8; pathological stage pT1-2; pre-operative PSA < 10 ng/ml). It is advised that therapy should not start before one year of follow-up after surgery and patients should be without PSA recurrence [138].

Patients who underwent brachytherapy or external beam radiation (EBRT) for low-risk prostate cancer can also be cautiously considered for testosterone treatment in case of symptomatic hypogonadism with a close monitoring of prostate cancer recurrence [136, 138, 139], although no long-term safety data are available in these patients.

5.6.3 Cardiovascular diseases

There is good evidence that testosterone deficiency, as well as erectile dysfunction, are both independent biomarkers, but not necessarily the cause, of cardiovascular disease and also for all-cause and cardiovascular

mortality [140]. Endogenous testosterone levels within the mid-normal range are associated with the lowest risk of mortality [92].

Two studies have reported that men with testosterone levels in the upper quartile of the normal range have a reduced number of cardiovascular events when compared to the combined data from the lower three quartiles [141, 142]. The knowledge that hypogonadism and erectile dysfunction are biomarkers of cardiovascular disease demonstrates that patients should be assessed for cardiovascular risk factors and where appropriate referred to cardiology. Individual cardiovascular risk factors (e.g. lifestyle, diet, exercise, smoking, hypertension, diabetes, dyslipidaemia) should be treated in men with pre-existing cardiovascular disease. Their secondary prevention should be optimised as best possible.

Testosterone treatment has also demonstrated in some studies beneficial effects on certain cardiovascular risk factors [143]. In men with angiographically proven coronary disease those with low testosterone are at greater risk of mortality [144, 145]. Over many years since testosterone treatment has been available up until recently, there have been no clinical studies in the medical literature, which have shown concern in regard to an increased risk of major cardiovascular events (MACE) apart from heart failure [146]. MACE is defined as the composite of cardiovascular death, non-fatal acute myocardial infarction, acute coronary syndromes, stroke and cardiac failure. However, three recent studies (one placebo-controlled trial [147] and two observational studies [148, 149] have suggested that testosterone treatment may be associated with an increased risk of cardiovascular events. These studies have recently been reviewed by the FDA who concluded that, 'each of the studies had major limitations, precluding the ability to draw definitive conclusions' [150]. These findings are supported by letters in response to the paper by Vigen et al. [151]. The controversy was fueled also by a metaanalysis by Xu et al. [152] of 27 small studies involving 2,994 predominantly older men that demonstrated that testosterone therapy increased the risk for cardiovascular-related events and that the effect of testosterone therapy was more dependent on the source of funding of the reported trials than on underlying baseline testosterone levels [153, 154]. However, other studies demostrated that testosterone treatment is at least not proatherogenic over a wide range of doses [155]. In order to overcome some of the limitations of the analysis of Xu et al., Corona et al. performed an updated systematic review and meta-analysis of RCTs on testosterone treatment, using a more conventional definition of cardiovascular events similar to that used by regulatory authorities to verify the safety of newly registered drugs (including MACE). The results do not support a causal role between testosterone treatment and adverse cardiovascular events [89].

Recent studies have provided some clarification in regard to the effect of testosterone treatment on cardiovascular events. A large (n=83,010, follow up mean > 4.7 years) retrospective study of men with low testosterone that had testosterone replaced to the normal range was associated with a reduction in myocardial infarction, whereas men treated with testosterone which did not achieve normalisation had no benefit [156]. A second retrospective analysis of MACE at three years (n=4,736) in men again treated to normalise testosterone compared groups with low, normal and high testosterone. The result was that normal testosterone reduced MACE and death [157]. A third large study (population-based matched cohort 10,311 TRT versus 28,029 controls) followed up for five years and reported that men with the highest tertile of testosterone treatment exposure decreased mortality and cardiovascular events whereas men in the lowest tertile of testosterone treatment exposure had increased mortality and cardiovascular events [94]. These studies demonstrate that when testosterone is used adequate replacement should be administered in order to normalise testosterone levels and that patients are compliant.

The European Medicines Agency (EMA) has stated 'The Co-ordination Group for Mutual Recognition and Decentralised Procedures - Human (CMDh), a regulatory body representing EU Member States, has agreed by consensus that there is no consistent evidence of an increased risk of heart problems with testosterone medicines in men who lack the hormone (a condition known as hypogonadism). However, the product information is to be updated in line with the most current available evidence on safety, and with warnings that the lack of testosterone should be confirmed by signs and symptoms and laboratory tests before treating men with these medicines.'

A recent comprehensive and detailed meta-analysis of available evaluable randomised placebo-controlled trials concluded that the data did not support a causal role between testosterone treatment and adverse cardiovascular events [89]. There are however no long-term studies or RCTs that provide a definitive answer. Observational studies have reported that testosterone treatment improves survival when compared to men who were not treated [69, 158]. These findings are supported by a large retrospective analysis of 6,355 men treated with testosterone compared to 19,065 non-users which did not demonstrate any increased risk of myocardial infarction with testosterone treatment [159].

Caution should, however, be used in men with pre-existing cardiovascular disease. Firstly, hypogonadism must be carefully diagnosed beyond reasonable doubt. Secondly, if testosterone is prescribed then testosterone levels should not exceed the mid-normal range and the haematocrit should not exceed 0.54 [160]. Testosterone dose adjustment may be required and/or venesection (500 mL) should be considered and repeated if necessary if the haematocrit is greater than 0.54. The haematocrit value of > 54 is based on the increased risk of cardiovascular mortality from the Framingham Heart Study [161], which was recently confirmed in another study [162]. This value is also supported by the known increased risk of thrombosis in the congenital condition of idiopathic erythropoiesis [163]. The majority of patients with cardiovascular disease will be receiving antiplatelet therapy. An electrocardiogram prior to testosterone treatment in the assessment of hypogonadism could be considered.

Two large retrospective studies have not shown any evidence that testosterone treatment is associated with an increased incidence of venous thromboembolism [164, 165]. Venous thromboembolism in one study of men on testosterone treatment reported 42 (38 men) cases, 40 of which had evidence of underlying thrombophilia (which included Factor V Leiden deficiency, prothrombin mutations, homocysteinuria) of which 39 had their condition diagnosed after an event [166]. In addition, high endogenous levels of testosterone and/or oestradiol are not associated with an increased risk of venous thromboembolism [164, 165, 167]. Testosterone treatment is contraindicated in men with severe chronic cardiac failure as fluid retention may lead to an exacerbation of the condition. Some studies including one of twelve months duration have shown that men with moderate chronic cardiac failure (NYHA class III) may benefit from low doses of testosterone, which achieve mid-normal range testosterone levels [75, 168, 169]. If a decision is made to treat hypogonadism in men with chronic cardiac failure it is essential that the patient is followed carefully with clinical assessment and testosterone and hematocrit measurements, on a regular basis. An interesting observation is that testosterone deficiency increased the re-admission and mortality rate in men with heart failure [93].

5.6.4 **Obstructive sleep apnoea**

There is no consistent evidence correlating testosterone treatment with obstructive sleep apnoea (OSA). There is also no evidence that testosterone treatment can result in the onset or worsening of the condition [170].

5.6.5 Anabolic steroid–induced hypogonadism

Non-prescription anabolic-androgenic steroids (AAS) are used in order to obtain a boost in athletic performances. Use of AAS results in hypogonadotropic hypogonadism by feedback suppression of the hypothalamic-pituitary-gonadal (HPG) axis via inhibition of pulsatile GnRH release and a subsequent decrease in LH and FSH. The duration of suppression and the resultant symptomatic hypogonadism is highly variable and due to multiple factors, including differences in the choices of drugs, amounts used, and durations of use. After a complete endocrine and metabolic assessment, the condition may be treated with hCG, and selective oestrogen receptor modulators (SERM) [171], until the reproductive endocrine axis has been restored.

5.7 Summary of evidence and recommendations on risk factors in testosterone replacement treatment

Summary of evidence	LE
Case reports and small cohort studies point to a possible correlation between testosterone treatment	3
and the onset of breast cancer, but there is as yet a lack of strong evidence for this relationship.	
Randomised controlled trials support the hypothesis that testosterone treatment does not result in	1b
changes in prostatic histology.	
Recent studies indicate that testosterone treatment does not increase the risk of prostate cancer, but	3
long-term follow-up data are not yet available.	
There is no evidence for a relationship between testosterone treatment and obstructive sleep apnoea.	3
There is no substantive evidence that testosterone treatment, when replaced to the normal	1a
physiological range, is related to the development of major adverse cardiovascular events.	
In hypogonadal men testosterone treatment has been demonstrated to have a positive impact on	1b
cardiovascular risks [89].	

Recommendations	LE	GR
Perform haematological, cardiovascular, breast and prostatic assessment before the start of	1a	А
treatment.		
Monitor testosterone, haematocrit, haemoglobin and prostate-specific antigen (PSA) during	3	А
testosterone treatment.		
Offer testosterone treatment cautiously in symptomatic hypogonadal men who have been	3	В
surgically treated for localised prostate cancer and who are currently without evidence of		
active disease (i.e. measurable PSA, abnormal rectal examination, evidence of bone/visceral		
metastasis): treatment should be restricted to those patients with a low risk for recurrent		
prostate cancer (i.e. Gleason score < 8; pathological stage pT1-2; pre-operative PSA < 10 ng/		
mL) and should not start before one year of follow-up.		
Assess for cardiovascular risk factors before commencing testosterone treatment and optimise	1a	А
secondary prevention in men with pre-existing cardiovascular disease.		
Treat men with hypogonadism and either pre-existing cardiovascular disease, venous	1b	А
thromboembolism or chronic cardiac failure who require testosterone treatment with caution		
by monitoring carefully with clinical assessment, haematocrit (not exceeding 0.54) and		
testosterone levels maintained as best possible for age within the mid-normal healthy range.		

6. FOLLOW-UP

6.1 Monitoring of patients receiving testosterone replacement therapy

Regular follow-up is needed in patients receiving testosterone treatment, as potentially androgen-dependent symptoms and conditions may occur. The side-effects of testosterone treatment are limited, but their incidence and clinical relevance is as yet unclear. The primary aim of testosterone treatment is to alleviate the clinical symptoms of testosterone deficiency. Careful monitoring of changes in the clinical manifestations of testosterone deficiency should therefore be an essential part of every follow-up visit. Effects of testosterone treatment on sexual interest may already appear after three weeks of treatment, and reach a plateau at six weeks [76]. Changes in erectile function and ejaculation may require up to six months [76]. Effects on QoL, and also on depressive mood, may become detectable within one month, but the maximum effect may take longer [76].

6.2 Testosterone level

There are as yet insufficient data to define optimal serum levels of testosterone during testosterone treatment. Expert opinion suggests that testosterone treatment should restore the serum testosterone level to the midnormal range of specific age groups of men, which is usually sufficient to alleviate various manifestations of hormone deficiency. An optimal monitoring schedule for serum testosterone level is also dependent on the formulation of testosterone used. It is of importance to evaluate symptom regression and lack of response prompts termination of treatment and eventual re-assessment of the diagnosis.

6.3 Bone density

Bone mineral density (BMD) should be monitored only in men whose BMD was abnormal before initiation of testosterone treatment. An increase in lumbar spine BMD may already be detectable after six months of treatment and may continue for three more years [76].

6.4 Haematocrit

It is important to use only minimal or no venous occlusion when taking a blood sample for haematocrit measurements [163]. Elevated haematocrit is the most frequent side-effect of testosterone treatment. The clinical significance of a high haematocrit level is unclear, but it may be associated with hyperviscosity and thrombosis [167]. The effect of erythropoiesis may become evident at three months and peaks at twelve months [76].

6.5 Prostate safety

Testosterone replacement therapy results in a marginal increase in PSA and prostate volume, plateauing at twelve months [76]. Previous fears that testosterone treatment might increase the risk of prostate cancer have been contradicted by a number of meta-analyses [107, 130, 134, 172]. However, there are insufficient long-term data available to conclude that there is safety regarding the development of prostate cancer with testosterone treatment. Prostate monitoring therefore remains indicated. Subjects with substantial or continuous increase of PSA level need to be investigated to exclude prostate cancer.

6.6 Cardiovascular monitoring

Caution should be used in men with pre-existing cardiovascular disease. In men with chronic heart failure, testosterone treatment can result in fluid retention and an exacerbation of the condition [168, 169]. If a decision is made to treat hypogonadism in men with chronic cardiac diseases it is essential that the patient is followed carefully with clinical assessment and testosterone and hematocrit measurements, on a regular basis.

6.7 Recommendations for follow-up

Recommendations	LE	GR
Assess the response to testosterone treatment at three, six and twelve months after the onset	4	С
of treatment, and thereafter annually.		
Monitor testosterone, haematocrit at three, six and twelve months and thereafter annually.	4	С
Decrease the testosterone dosage or switch testosterone preparation from parenteral to topical		
or venesection, if haematocrit is above 0.54. If haematocrit remains elevated, stop testosterone		
and reintroduce at a lower dose once haematocrit has normalised.		
Assess prostate health by digital rectal examination and prostate-specific antigen (PSA) before	4	С
the start of testosterone replacement therapy (TRT). Follow-up by PSA tests at three, six and		
twelve months and thereafter annually.		
Assess men with cardiovascular diseases for cardiovascular symptoms before testosterone	1b	А
treatment is initiated and continue close clinical assessment during treatment.

8. CONFLICT OF INTEREST

All members of the EAU Male Hypogonadism Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <u>http://www.uroweb.org/guideline/</u>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Urological Infections Guidelines Panel has compiled these clinical guidelines to provide medical professionals with evidence-based information and recommendations for the prevention and treatment of urological tract infections (UTIs). These guidelines also aim to address the important public health aspects of infection control and antimicrobial stewardship. Separate EAU guidelines documents are available addressing paediatric urological infections [1] and infections in patients with neurological urinary tract dysfunction [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urological Infections Guidelines Panel consists of a multi-disciplinary group of urologists, with particular expertise in this area, and an infectious disease specialist. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: <u>http://uroweb.org/guideline/urological-infections/</u>.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions, which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: <u>http://uroweb.org/guideline/urologicalinfections/</u>.

1.4 Publication history

The Urological Infections Guidelines were first published in 2001. The 2016 document consisted of the first completed sections of an entirely new Urological Infections Guideline formulated following new EAU guideline production methodology. This 2017 document is an amalgamation of the 2015 and 2016 Guidelines and will be updated over the coming year to cover all key clinical questions related to UTIs.

2. METHODS

2.1 Introduction

For the 2017 Urological Infections Guidelines, specific chapters were updated based on systematic reviews of topics or questions prioritised by the Guideline Panel. These reviews were performed using standard Cochrane systematic review methodology, <u>http://www.cochranelibrary.com/ about/about-cochrane-systematicreviews.</u> <u>html</u>.

Systematic review results for the following evidence questions are included in the 2017 Urological Infections Guidelines:

- 1. What is the most effective management for adults with asymptomatic bacteriuria [3]?
- 2. What is the best antimicrobial prophylaxis strategy to reduce risk of infectious complication of prostate biopsy [4]?

References used in this text are graded according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [5]. Additional information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://www.uroweb.org/guideline/</u>. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

This document was subject to independent peer review prior to publication in 2015 and 2016.

3. THE GUIDELINE

3.1 Classification

Different classification systems of UTI exist. Most widely used are those developed by the Centers for Disease Control and Prevention (CDC) [6], Infectious Diseases Society of America (IDSA) [7], European Society of Clinical Microbiology and Infectious Diseases (ESCMID) [8] as well as the U.S. Food and Drug Administration (FDA) [9, 10]. Current UTI guidelines frequently use the concept of uncomplicated and complicated UTI with a number of modifications (Figure 1). In 2011 the EAU/EAU Section of Infections in Urology proposed the ORENUC classification system based on the clinical presentation of the UTI, categorisation of risk factors and availability of appropriate antimicrobial therapy [11].

Figure 1 – Concept of uncomplicated and complicated UTI

The following classification of UTIs is adopted in the EAU Urological Infections Guidelines:

Classification of UTI	
Uncomplicated UTIs	Acute, sporadic or recurrent lower (uncomplicated cystitis) and/or upper (uncomplicated pyelonephritis) UTI, limited to non-pregnant, pre- menopausal women with no known anatomical and functional abnormalities within the urinary tract or comorbidities.
Complicated UTIs	All UTIs which are not defined as uncomplicated. Meaning in a narrower sense UTIs in a patient with an increased chance of a complicated course: i.e. all men, pregnant women, patients with anatomical or functional abnormalities of the urinary tract, indwelling urinary catheters, renal diseases, and/or with other concomitant immunocompromising diseases for example, diabetes.
Recurrent UTIs	Recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months.
Catheter-associated UTIs	Catheter-associated urinary tract infection (CA-UTI) refers to UTIs occurring in a person whose urinary tract is currently catheterised or has been catheterised within the past 48 hours.
Urosepsis	A systemic, deleterious host response to infection originating from the urinary tract and/or male genital organs. Urosepsis is accompanied by signs of systemic inflammation, presence of symptoms of organ dysfunction and persistent hypotension associated with tissue anoxia.

3.2 Antimicrobial stewardship

Antimicrobial stewardship programmes aim to optimise the outcome of prevention and treatment of infection whilst curbing overuse and misuse of antimicrobial agents [12-16]. Measures of success include regulating antimicrobial prescribing, and reduction in both the rate of healthcare associated infections such as *Clostridium difficile* and the emergence of resistant organisms [16]. In urology, antimicrobial stewardship programmes should include a series of measures to ensure rational, evidence based use of antimicrobials in the prevention and treatment of infections of the urinary tract and male accessory glands, as well as non-antimicrobial strategies. Programmes require a stewardship team approach comprising urologists, infectious diseases

physicians, microbiologists and clinical pharmacologists or pharmacists [13-16].

The most important components of antimicrobial stewardship programmes are [14]:

- regular training of staff in best use of antimicrobial agents;
- adherence to local, national or international guidelines;
- regular ward visits and consultation with infectious diseases physicians, with audit;
- treatment outcome evaluation;
- monitoring and regular feedback to prescribers of their antimicrobial prescribing performance and local pathogen resistance profiles.

Several studies in hospital settings have shown that regular ward visits and audit of practice by infectious disease physicians markedly reduce overall use of antimicrobial agents by promoting shorter duration of therapy, earlier step-down to oral medication and avoidance of antimicrobial use when patient outcome is unlikely to be compromised [16, 17]. Studies specific to the urology setting are lacking but a case-control study showed reduction in antimicrobial usage and bacterial resistance in hospitalised urology patients when EAU Guidelines on peri-operative prophylaxis were adhered to, without change in the rate of infectious complications [18].

3.3 Asymptomatic bacteriuria in adults

3.3.1 Evidence question

What is the most effective management for people with asymptomatic bacteriuria?

3.3.2 Background

Urinary growth of bacteria in an asymptomatic individual, asymptomatic bacteriuria (ABU), is common, and relates to commensal colonisation [19]. Clinical studies have shown that ABU may protect against superinfecting symptomatic UTI, therefore, treatment of ABU should be performed only in cases of proven benefit for the patient to avoid the risk of selecting for antimicrobial resistance and eradicating a potentially protective ABU strain [20, 21]. The aim of this section is to support the clinician in deciding when ABU should or should not be treated.

3.3.3 Epidemiology, aetiology and pathophysiology

Asymptomatic bacteriuria occurs in an estimated 1-5% of healthy pre-menopausal females, increasing to 4-19% in otherwise healthy elderly females and men, 0.7-27% in patients with diabetes, 2-10% in pregnant women, 15-50% in institutionalised elderly populations, and 23-89% in patients with spinal cord injuries [22]. Asymptomatic bacteriuria in younger men is uncommon, but when detected, chronic bacterial prostatitis must be considered. The spectrum of bacteria in ABU is similar to species found in uncomplicated or complicated UTIs, depending on the presence of risk factors (see sections 3.4 and 3.7).

3.3.4 Diagnostic evaluation

Asymptomatic bacteriuria in an individual without urinary tract symptoms is defined by a mid-stream sample of urine (MSU), showing bacterial growth $\ge 10^5$ cfu/mL, in two consecutive samples in women [23] and in a single sample in men [24]. In a single catheterised sample bacterial growth may be as low as 10^2 cfu/mL to be considered representing true bacteriuria in both men and women [22, 25]. Diagnostic work-up should include measurement of residual urine. Cystoscopy and/or imaging of the upper urinary tract is not mandatory if the patient's medical history is otherwise without remark. If persistent growth of urease producing bacteria, *i.e. Proteus mirabilis* is detected, stone formation in the urinary tract must be excluded [26]. In men, a digital rectal examination (DRE) has to be performed to rule out prostate diseases (see section 3.11).

3.3.5 Evidence summary

A systematic search of the literature from January 2000 to September 2016 identified 2,853 titles of which 218 titles were selected for full text review, 61 of these texts were included in the final review [21, 27-83]. For the subgroups of pregnancy, patients scheduled for urologic surgeries, post-menopausal women and institutionalised elderly patients only data from randomised-controlled trials (RCT) was included, on which a meta-analysis was performed. For the remaining subgroups non-RCTs were also included in a narrative synthesis of the evidence. The following patient populations were not covered by the systematic review: immuno-comprised patients, patients with candiduria, dysfunctional and/or reconstructed lower urinary tracts and patients with indwelling catheters.
3.3.6 Disease management

3.3.6.1 Patients without identified risk factors

Asymptomatic bacteriuria does not cause renal disease or damage [84]. Only one prospective, non-randomised study investigated the effect of treatment of ABU in adult, non-diabetic, non-pregnant women [61], and found no difference in the rate of symptomatic UTIs. Furthermore, as the treatment of ABU has been proven to be unnecessary in high-risk patient subgroups, there is panel consensus that the results of these subgroups can also be applied to patients without identified risk factors. Therefore, screening and treatment of ABU is not recommended in patients without risk factors.

3.3.6.2 Patients with ABU and recurrent UTI, otherwise healthy

One RCT investigated the effect of ABU treatment in female patients with recurrent symptomatic UTI and without identified risk factors [21] and demonstrated that treatment of ABU increases the risk of a subsequent symptomatic UTI episode, as compared to non-treated patients (RR 0.28, 95% CI 0.21 to 0.38; 673 patients). This protective effect of spontaneously developed ABU can be used as part of prevention in female patients with recurrent symptomatic UTI. Therefore, treatment of ABU is not recommended. However, occasionally the eradication of a strain considered the causative agent of recurrent episodes of UTI, may be justified. In men with recurrent symptomatic UTI and ABU, chronic bacterial prostatitis must be considered and, if diagnosed, treated (see chapter 3.11).

3.3.6.3 Pregnant women

3.3.6.3.1 Is treatment of ABU beneficial in pregnant women?

Twelve RCTs comparing antimicrobial treatment of ABU with placebo controls or no treatment [27, 29, 38, 39, 42, 44, 45, 48, 50, 54, 55, 57], with different antibiotic doses and regimens were identified. Eleven RCTs (n=2,002) reported on the rate of symptomatic UTIs [27, 29, 33, 38, 42, 44, 45, 48, 50, 54, 55]. Antibiotic treatment significantly reduced the number of symptomatic UTIs compared to placebo or no treatment (average (RR) 0.20, 95% CI 0.10 to 0.39).

Six RCTs reported on the resolution of bacteriuria [38, 39, 42, 44, 50, 55]. Antibiotic treatment was effective in the resolution of bacteriuria compared to placebo (average RR 2.99, 95% Cl 1.65 to 5.39; n=716). Eight RCTs reported on the rate of low birthweights [27, 33, 38, 42, 44, 45, 54, 57]. Antibiotic treatment was associated with lower rates of low birthweight compared to placebo or no treatment (average RR 0,58, 95% Cl 0.36 to 0.94; n=1,689). Four RCTs reported on the rate of pre-term deliveries [33, 54, 55, 57]. Antibiotic treatment was associated with lower rate of pre-term delivery compared to placebo or no treatment (average RR 0,34, 95% Cl 0.18 to 0.66; n-854).

Based on the beneficial maternal and fetal effects of antibiotic treatment pregnant women should be screened and treated for ABU. However, the panel would like to emphasise that most available studies have low methodological quality and are from the 60's to 80's. Diagnostic and treatment protocols and accessibility to medical services has dramatically changed since then; therefore, the quality of evidence for this recommendation is low. In newer studies of higher methodological quality the beneficial effects of antibiotic treatment are not as evident [33]. Therefore, it is advisable to also consult national recommendations for the treatment of ABU in pregnant women.

3.3.6.3.2 Which treatment duration should be applied to treat ABU in pregnancy?

Sixteen RCTs comparing the efficacy of different antibiotic treatments in pregnant women with ABU were identified [28, 32, 34-37, 40, 41, 43, 46, 47, 49, 51-53, 56]. There was significant heterogeneity amongst the studies. Studies compared different antibiotic regimens or the same antibiotic regimens with different durations. The duration of treatment ranged from single dose to continuous treatment (until delivery). For practical purposes the grouping strategy used by the previously published Cochrane Review by Widmer et. al., was adopted with some modifications [85]. The following treatment groups were used for comparison:

- 1. single dose (single day);
- 2. short course (2-7 days);
- 3. long course (8-14 days);
- 4. continuous (until delivery).

Nine studies compared single dose to short course treatment [28, 34, 35, 40, 41, 46, 47, 49, 53], one study compared single dose to long course treatment [52] and one study compared long course to continuous treatment [56]. As long term and continuous antibiotic treatment is not used in current practice, only studies comparing single dose to standard short course treatment are presented.

3.3.6.3.2.1 Single dose vs. short course treatment

Three RCTs reported on the rate of symptomatic UTIs [34, 40, 46], with no significant difference between the two durations (average RR 1.00, 95% CI 0.58 to 1.71; n=891). Nine RCTs reported on the rate of ABU resolution [28, 34, 35, 40, 41, 46, 47, 49, 53], with no significant difference between the two durations (average RR 0.95, 95% CI 0.90 to 1.01; 1268 women). Six RCTs reported on the rate of side effects [34, 35, 40, 41, 49, 53]. Single dose treatment was associated with significantly less side effects compared to short course treatment (average RR 0.34, 95% CI 0.19 to 0.62; 458 women). Three RCTs reported on the rate of pre-term deliveries [34, 46, 51], with no significant difference between the two durations (average RR 1.15, 95% CI 0.75 to 1.76; 814 women). One RCT reported on the rate of low birthweights [46]. There were significantly more babies with low birthweight in the single dose regimen compared to short course treatment (average RR 1.65, 95% CI 1.06 to 2.57; 714 women).

According to the data analysis, single dose treatment was associated with a significantly lower rate of side effects but a significantly higher rate of low birthweight. Therefore, standard short course treatment should be applied to treat ABU in pregnancy, however it should be emphasised that the overall quality of the scientific evidence backing this recommendation is low.

3.3.6.4 Patients with identified risk-factors

3.3.6.4.1 Diabetes mellitus

Diabetes mellitus, even when well regulated, is reported to correlate to a higher frequency of ABU [86]. One RCT demonstrated that eradicating ABU did not reduce the risk of symptomatic UTI and infectious complications in patients with diabetes mellitus. The time to first symptomatic episode was also similar in both groups. Furthermore, untreated ABU did not correlated to diabetic nephropathy [87]. Screening and treatment of ABU in well-regulated diabetes mellitus is therefore not recommended. However, poorly regulated diabetes is a risk factor for symptomatic UTI and infectious complications.

3.3.6.4.2 ABU in post-menopausal women

Elderly women have an increased incidence of ABU [88]. Four RCTs compared antibiotic treatment of ABU with placebo controls or no treatment, in a post-menopausal female population, with different antibiotic doses and regimens [65-67, 70]. Women in these studies were mostly nursing home residents, which may bias the results of this analysis. Three RCTs reported on the rate of symptomatic UTIs (average RR 0.71, 95% CI 0.49 to 1.05; 208 women) and the resolution of bacteriuria (average RR 1.28, 95% CI 0.50 to 3.24; 203 women) [34, 40, 46], with no significant benefit of antibiotic treatment. Therefore, ABU in post-menopausal women does not require treatment, and should be managed as for pre-menopausal women.

3.3.6.4.3 Elderly institutionalised patients

The rate of ABU is 15-50% in elderly institutionalised patients [89]. Differential diagnosis of ABU from symptomatic UTI is difficult in the multi-diseased and mentally deteriorated patient, and is probably a cause of unnecessary antibiotic treatment [90, 91]. Seven RCTs compared antibiotic treatment of ABU with placebo controls or no treatment in elderly patients, with different antibiotic doses and regimens [63, 65-67, 70, 72, 73].

Three RCTs reported on the rate of symptomatic UTIs [63, 65, 67]. Antibiotic treatment was not significantly beneficial in reducing the rate of symptomatic UTIs compared to placebo or no treatment (average RR 0.68, 95% CI 0.46 to 1.00; 210 patients). Six RCTs reported on the resolution of bacteriuria [63, 65, 67, 70, 72, 73]. There was no benefit of antibiotic treatment compared to placebo in the resolution of ABU (average RR 1.33, 95% CI 0.63 to 2.79; 328 patients). One RCT compared the rates of incontinence in this patient group before and after the eradication of ABU, and found no effect of antibiotic treatment [71]. Therefore, screening and treatment of ABU is not recommended in this patient group.

3.3.6.4.4 Patients with renal transplants

One RCT, one prospective non-randomised and two retrospective studies compared the effect of antibiotic treatment to no treatment in renal transplant patients [74-76, 80]. None of the studies found antibiotic treatment beneficial in terms of reducing the rate of ABU or symptomatic UTIs. Furthermore, there were no significant differences in the rate of graft loss or change in renal function during long-term follow-up [74-76, 80]. Therefore, treatment of ABU is not recommended in renal transplant recipients.

3.3.6.4.5 Patients with dysfunctional and/or reconstructed lower urinary tracts

Patients with lower urinary tract dysfunction (LUTD) (e.g. neurogenic bladder patients secondary to multiple sclerosis, spinal cord injury patients, patients with incomplete bladder emptying, patients with neo-bladder and ileo-cystoplasty, patients using clean intermittent catheterisation (CIC), and patients with ileal conduits, orthotopic bladder replacement and continent reservoirs) frequently become colonised [92, 93]. Studies have shown no benefit in ABU treatment in these patient groups [92, 94]. Furthermore, in LUTD patients who do not

spontaneously develop ABU, deliberate colonisation with an ABU strain (*Escherichia coli* 83972) has shown a protective effect against symptomatic recurrences [95, 96]. Screening and treatment of ABU in these patient groups is therefore, not recommended. If these patient groups develop recurrent symptomatic UTI (see section 3.5) the potential protective effect of a spontaneously developed ABU against lower UTI must be considered before any treatment.

3.3.6.4.6 Patients with catheters in the urinary tract

Patients with indwelling or suprapubic catheters, and nephrostomy tubes, invariably become carriers of ABU, with antibiotic treatment showing no benefit. This is also applicable for patients with ABU and indwelling ureteral stents [97]. Routine treatment of catheter associated bacteriuria is not recommended. For detailed recommendations see section 3.8.

3.3.6.4.7 Patients with ABU subjected to catheter placements/exchanges

In patients subjected to uncomplicated placement/exchanges of indwelling catheters ABU is not considered a risk factor in itself, and should not be screened or treated [98]. In patients subjected to placement/ exchanges of nephrostomy tubes and indwelling ureteral stents, ABU is considered a risk factor for infectious complications [99]. Therefore, screening and treatment prior to the procedure is recommended.

3.3.6.4.8 Immuno-comprised and severely diseased patients, patients with candiduria

These patient groups have to be considered individually and the benefit of screening and treatment of ABU should be reviewed in each case. Patients with asymptomatic candiduria may, but not necessarily, have an underlying disorder or defect. Treatment of asymptomatic candiduria is not recommended in patients with an otherwise uncomplicated medical history [100].

3.3.6.5 Prior to urological surgery

In diagnostic and therapeutic procedures not entering the urinary tract, ABU is generally not considered as a risk factor, and screening and treatment are not considered necessary. On the other hand, in procedures entering the urinary tract and breaching the mucosa, particularly in endoscopic urological surgery, bacteriuria is a definite risk factor.

Two RCTs [78, 81] and two prospective non-randomised studies [82, 83] compared the effect of antibiotic treatment to no treatment prior to transurethral prostate or bladder tumour resection. Antibiotic treatment significantly reduced the number of post-operative symptomatic UTIs compared to no treatment in the meta-analysis of the two RCTs (average RR 0.19, 95% CI 0.05 to 0.82; 167 patients). The rates of post-operative fever and septicaemia were also significantly lower in case of antibiotic treatment compared to no treatment in the two RCTs.

A urine culture must therefore be taken prior to such interventions and in case of ABU, pre-operative treatment should be given. The recommendations for antibiotic prophylaxis in different urological procedures are given in section 3.15.

3.3.6.6 Prior to orthopaedic surgery

One RCT and one multicentre cohort study comparing the treatment of ABU with no treatment prior to orthopaedic surgery (hip arthroplasty/hemiarthroplasty or total knee arthroplasty) were identified [101, 102]. None of the studies showed a beneficial effect of antibiotic treatment in terms of prosthetic joint infection. One study measured the rate of post-operative symptomatic UTIs and found no significant difference between antibiotic treatment and no treatment [102]. Therefore, treatment of bacteriuria is not recommended prior to arthroplasty surgery.

3.3.6.7 Pharmacological management

If the decision is taken to eradicate ABU, the same choice of antibiotics and treatment duration as in symptomatic uncomplicated (section 3.4.4.4) or complicated (section 3.7.5) UTI could be given, depending on gender, medical background and presence of complicating factors. Treatment should be tailored and not empirical. Based on clinical experience, if ABU patients complain of odour and mild dysuria, methenamine hippurate 1 g two to three times daily, and/or increased water intake, may be considered.

3.3.7 Follow-up

There are no studies focusing on follow-up after treatment of ABU. However, if the resolution of ABU has a clinical significance (e.g. in pregnancy), follow-up with subsequent urine culture is needed to secure the treatment effect.

3.3.8 Recommendations for the management of ABU

		1
Recommendations	LE	GR
Do not screen or treat asymtomatic bacteriuria in the following conditions:		
women without risk factors;	2a	A*
 patients with well-regulated diabetes mellitus; 	1b	A
post-menopausal women;	1a	A
elderly institutionalised patients;	1a	A
 patients with dysfunctional and/or reconstructed lower urinary tracts; 	2b	В
 patients with catheters in the urinary tract; 	4	С
patients with renal transplants;	1b	A
 patients prior to arthoplasty surgeries; 	1b	A
patients with recurrent urinary tract infections.	1b	A
Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the	1a	A
mucosa.		
Screen for and treat asymptomatic bacteriuria in pregnant women with standard short course		
treatment.		
Take a urine culture following treatment of asymptomatic bacteriuria to secure treatment effect.	4	С

3.4 Uncomplicated cystitis

3.4.1 Introduction

Uncomplicated cystitis is defined as acute, sporadic or recurrent cystitis limited to non-pregnant, premenopausal women with no known anatomical and functional abnormalities within the urinary tract or comorbidities.

3.4.2 Epidemiology, aetiology and pathophysiology

Almost half of all women will experience at least one episode of cystitis during their lifetime. Nearly one in three women will have had at least one episode of cystitis by the age of 24 years [103]. Risk factors include sexual intercourse, use of spermicide, a new sexual partner, a mother with a history of UTI and a history of UTI during childhood. The spectrum of aetiological agents is similar in uncomplicated cystitis and pyelonephritis, with *E. coli* being the causative pathogen in 70-95% of cases and *Staphylococcus saprophyticus* in 5-10%. Occasionally, other Enterobacteriaceae, such as *P. mirabilis* and *Klebsiella spp.*, are isolated [104].

3.4.3 Diagnostic evaluation

3.4.3.1 Clinical diagnosis

The diagnosis of uncomplicated cystitis can be made with a high probability based on a focused history of lower urinary tract symptoms (dysuria, frequency and urgency) and the absence of vaginal discharge or irritation [105, 106]. In elderly women genitourinary symptoms are not necessarily related to cystitis [107].

3.4.3.2 Differential diagnosis

Uncomplicated cystitis should be differentiated from ABU, which is considered not to be infection but rather a commensal colonisation, which should not be treated and therefore not screened for, except if it is considered a risk factor in clearly defined situations see section 3.3.

3.4.3.3 Laboratory diagnosis

Urine dipstick testing is a reasonable alternative to culture for diagnosis of uncomplicated cystitis [108, 109]. Urine cultures are recommended in the following situations:

- suspected acute pyelonephritis;
- symptoms that do not resolve or recur within two to four weeks after the completion of treatment;
- women who present with atypical symptoms [110, 111];
- pregnant women;
- males with suspected UTI.

A colony count of 10³ cfu/mL of uropathogens is microbiologically diagnostic in women who present with symptoms of uncomplicated cystitis [112]. Women who present with atypical symptoms of either uncomplicated cystitis or uncomplicated pyelonephritis, as well as those who fail to respond to appropriate antimicrobial therapy should be considered for additional diagnostic studies.

3.4.3.4 Recommendations for the diagnostic evaluation of uncomplicated cystitis

Recommendations	LE	GR	
Diagnose uncomplicated cystitis based on:	2a	В	
• a focused history of lower urinary tract symptoms (dysuria, frequency and urgency);			
• the absence of vaginal discharge or irritation, in women who have no other risk factors for			
complicated urinary tract infections.			
Use urine dipstick testing, as an alternative to culture for diagnosis of acute uncomplicated			
cystitis.			
Urine cultures should be done in the following situations:	4	B*	
suspected acute pyelonephritis;			
• symptoms that do not resolve or recur within two-four weeks after the completion of			
treatment;			
women who present with atypical symptoms;			
• pregnant women.			

* Upgraded based on panel consensus

3.4.4 Disease management

Antimicrobial therapy is recommended because clinical success is significantly more likely in women treated with antimicrobials compared with placebo [113]. The choice of antimicrobial therapy should be guided by [105]:

- spectrum and susceptibility patterns of the aetiological pathogens;
- efficacy for the particular indication in clinical studies;
- tolerability and adverse reactions;
- adverse ecological effects;
- costs;
- availability.

According to these principles and the available susceptibility patterns in Europe, fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg three times a day for three to five days, and nitrofurantoin macrocrystal 100 mg twice daily for 5 days, are considered as drugs of first choice, when available [114-116].

Alternative antimicrobials include trimethoprim alone or combined with a sulphonamide. Co-trimoxazole (160/800 mg twice daily of three days) or trimethoprim (200 mg twice daily for five days) should only be considered as drugs of first choice in areas with known resistance rates for *E. coli* of < 20% [117, 118]. Despite lower resistance rates in certain countries, fluoroquinolones are not considered first choice because of adverse effects including negative ecological effects and selection for resistance.

Aminopenicillins are no longer suitable for empirical therapy because of worldwide high *E. coli* resistance. Aminopenicillins in combination with a beta-lactamase inhibitor such as ampicillin/sulbactam or amoxicillin/clavulanic acid and oral cephalosporins are in general not effective as short-term therapy and are not recommended for empirical therapy due to ecological collateral damage, but may be used in selected cases [119, 120].

3.4.4.1 Cystitis in pregnancy

Short courses of antimicrobial therapy can also be considered for treatment of cystitis in pregnancy [121], but not all antimicrobials are suitable during pregnancy. In general penicillins, cephalosporins, fosfomycin, nitrofurantoin (not in case of glucose-6-phosphate dehydrogenase deficiency and during the end of pregnancy), trimethoprim (not in the first trimenon) and sulphonamides (not in the last trimenon), can be considered.

3.4.4.2 Cystitis in men

Uncomplicated cystitis without involvement of the prostate is uncommon, and therefore treatment with antimicrobials penetrating into the prostate tissue is needed in males with symptoms of UTI. A treatment duration of at least seven days is recommended, preferably with trimethoprim sulphamethoxazole or a fluoroquinolone if in accordance with susceptibility testing (see section 3.4.4.4) [122].

3.4.4.3 Renal insufficiency

In patients with renal insufficiency the choice of antimicrobials may be influenced by decreased renal excretion. However, most antimicrobials, have a wide therapeutic index. No adjustment of dose is necessary until glomerular filtration rate (GFR) is < 20 mL/min, except for antimicrobials with nephrotoxic potential, e.g. aminoglycosides. Combination of loop diuretics (e.g. furosemide) and a cephalosporin is nephrotoxic. Nitrofurantoin and tetracyclines are contraindicated, but not doxycycline [122].

Recommendations					
Antimicrobial	Daily dose	Duration of Comments therapy		LE	GR
First choice					
Fosfomycin trometamol	3 g SD	1 day	Recommended in women not men.	1	A
Nitrofurantoin macrocrystal	100 mg b.i.d	5 days			
Pivmecillinam	400 mg t.i.d	3-5 days			
Alternatives					
Cephalosporins (e.g. cefadroxil)	500 mg b.i.d	3 days	Or comparable.	1b	В
If the local resistance p	oattern for E. coli i	s < 20%			
Trimethoprim	200 mg b.i.d	5 days	Not in the first trimenon of pregnancy.	1b	В
Trimethoprim-	160/800 mg b.i.d	3 days	Not in the last trimenon of		
sulphamethoxazole			pregnancy.		
Treatment in men					
Trimethoprim- sulphamethoxazole	160/800 mg b.i.d	7 days	Restricted to men, fluoroquinolones can also be prescribed in accordance with local susceptibility testing.	4	С

3.4.4.4 Recommendations for antimicrobial therapy for uncomplicated cystitis

SD = single dose; *b.i.d* = twice daily; *t.i.d* = three times daily.

3.4.5 **Follow-up**

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated [123]. In women whose symptoms do not resolve by end of treatment, and in those whose symptoms resolve but recur within two weeks, urine culture and antimicrobial susceptibility testing should be performed [124]. For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a seven day regimen using another agent should be considered [124].

3.5 Recurrent UTIs

3.5.1 Introduction

Recurrent UTIs (rUTIs) are recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months. Although rUTIs include both lower tract infection (cystitis) and upper tract infection (pyelonephritis), repeated pyelonephritis should prompt consideration of a complicated aetiology.

3.5.2 Diagnostic evaluation

Recurrent UTIs are common. Risk factors are outlined in Table 1. Diagnosis of rUTI should be confirmed by urine culture. An extensive routine workup including cystoscopy, imaging, etc. is not routinely recommended as the diagnostic yield is low [125]. However, it should be performed without delay in atypical cases, for example, if renal calculi or outflow obstruction is suspected.

Table 1: Age-related risk factors for rUTI in women [89, 107, 126]

Young and pre-menopausal women	Post-menopausal and elderly women
Sexual intercourse	History of UTI before menopause
Use of spermicide	Urinary incontinence
A new sexual partner	Atrophic vaginitis due to oestrogen deficiency
A mother with a history of UTI	Cystocoele
History of UTI during childhood	Increased post-void urine volume
Blood group antigen secretory status	Blood group antigen secretory status
	Urine catheterisation and functional status
	deterioration in elderly institutionalised women

3.5.3 Disease management and follow-up

Prevention of rUTIs includes counselling regarding avoidance of risk factors, non-antimicrobial measures and antimicrobial prophylaxis [124]. These interventions should be attempted in this order. Any urological risk factors must be identified and treated. Significant residual urine should be treated optimally, including by clean intermittent catheterisation when judged to be appropriate.

3.5.3.1 Behavioural modifications

A number of behavioural and personal hygiene measures (e.g. reduced fluid intake, habitual and post-coital delayed urination, wiping from back to front after defection, douching and wearing occlusive underwear) have been suggested to decrease the risk of rUTI. However, studies that have explored these risk factors have consistently documented the lack of association with rUTI [124].

3.5.3.2 Non-antimicrobial prophylaxis

There are many non-antimicrobial measures recommended for rUTIs but only a few are supported by well-designed studies [127, 128].

3.5.3.2.1 Hormonal replacement

In post-menopausal women vaginal oestrogen replacement, but not oral oestrogen, showed a trend towards preventing rUTI [127, 129].

3.5.3.2.2 Immunoactive prophylaxis

OM-89 (Uro-Vaxom[®]) is sufficiently well documented and has been shown to be more effective than placebo in several randomised trials with a good safety profile. Therefore, it can be recommended for immunoprophylaxis in female patients with rUTIs [127, 130-132]. Efficacy in other groups of patients and relative to antimicrobial prophylaxis remains to be established.

The vaginal vaccine Urovac[®] slightly reduced rUTIs. Primary immunisation followed by booster immunisation increased time to re-infection [127].

3.5.3.2.3 Prophylaxis with probiotics (Lactobacillus spp.)

Pooled data from a recent meta-analysis shows no convincing benefit of lactobacillus products as prophylaxis for rUTI [133]. However, differences in effectiveness between available preparations suggest further trials are needed before any definitive recommendation for or against their use can be made.

3.5.3.2.4 Prophylaxis with cranberry

Limited studies have suggested that cranberry is useful in reducing the rate of lower UTIs in women [134, 135]. However, a meta-analysis including 24 studies and comprising 4,473 participants showed that cranberry products did not significantly reduce the occurrence of symptomatic UTI for women with rUTI [136]. Due to these contradictory results, no recommendation on the daily consumption of cranberry products can be made.

3.5.3.2.5 Prophylaxis with D-mannose

In a randomised placebo-controlled non-blinded clinical trial, it was shown that a daily dose of 2 g D-mannose was significantly superior to placebo and as effective as 50 mg nitrofurantoin in preventing rUTI [137]. This is indicative but not sufficient for a recommendation therefore, D-mannose should at present only be used within the context of clinical investigations.

3.5.3.2.6 Endovesical instillation

Endovesical instillation of hyaluronic acid and chondroitin sulphate have been used for glycosaminoglycan

(GAG) layer replenishment in the therapy of interstitial cystitis, overactive bladder, radiation cystitis, and for prevention of rUTI [138]. A recent review of 27 clinical studies concluded that large-scale trials are urgently needed to assess the benefit of this type of therapy [139]. Therefore, no general recommendation is possible at this stage.

3.5.3.3 Antimicrobials for preventing rUTI

3.5.3.3.1 Continuous low-dose antimicrobial prophylaxis and post-coital prophylaxis

Antimicrobials may be given as continuous low-dose prophylaxis for longer periods (three to six months), or as post-coital prophylaxis, as both regimens reduce the rate of rUTI [140]. It is mandatory to offer both options after counselling, and when behavioural modifications and non-antimicrobial measures have been unsuccessful. Regimens include nitrofurantoin 50 mg or 100 mg once daily, fosfomycin trometamol 3 g every ten days, and during pregnancy cephalexin 125 mg or 250 mg or cefaclor 250 mg once daily [124]. Post-coital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI [141].

3.5.3.3.2 Self-diagnosis and self-treatment

In patients with good compliance, self-diagnosis and self-treatment with a short course regimen of an antimicrobial agent should be considered [142]. The choice of antimicrobials is the same as for sporadic acute uncomplicated UTI (section 3.4.4.4).

3.5.4 **Recommendations for the diagnostic evaluation and treatment of rUTIs**

Recommendations	LE	GR
Do not perform an extensive routine workup in women with recurrent UTI without risk factors.	1b	В
Advise patients on behavioural modifications which might reduce the risk of recurrent UTI.	3	С
Use vaginal oestrogen replacement in post-menopausal women to prevent recurrent UTI.	1b	А
Use immunoactive prophylaxis to reduce recurrent UTI in all age groups.	1a	А
When non-antimicrobial interventions have failed, continuous or post-coital antimicrobial	2b	В
prophylaxis should be used to prevent recurrent UTI, but patients should be counselled		
regarding possible side effects.		
For patients with good compliance, self-administrated short term antimicrobial therapy should	2b	A*
be considered.		

* Upgraded based on panel consensus.

3.6 Uncomplicated pyelonephritis

Uncomplicated pyelonephritis is defined as pyelonephritis limited to non-pregnant, pre-menopausal women with no known urological abnormalities or comorbidities.

3.6.1 Diagnostic evaluation

3.6.1.1 Clinical diagnosis

Pyelonephritis is suggested by fever (> 38°C), chills, flank pain, nausea, vomiting, or costovertebral angle tenderness, with or without the typical symptoms of cystitis [143]. Pregnant women with acute pyelonephritis need special attention, as this kind of infection may have not only an adverse effect on the mother with anaemia, renal and respiratory insufficiency, but also on the unborn child with more frequent pre-term labour and birth [144].

3.6.1.2 Differential diagnosis.

It is vital to differentiate as soon as possible between uncomplicated and complicated mostly obstructive pyelonephritis, as the latter can rapidly lead to urosepsis. This differential diagnosis should be made by the appropriate imaging technique (see section 3.6.1.4).

3.6.1.3 Laboratory diagnosis

Urinalysis including the assessment of white and red blood cells and nitrite, is recommended for routine diagnosis [145]. In addition, urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis.

3.6.1.4 Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound (US) should be performed to rule out urinary obstruction or renal stone disease [146]. Additional investigations, such as an unenhanced helical computed tomography

(CT), excretory urography, or dimercaptosuccinic acid (DMSA) scanning, should be considered if the patient remains febrile after 72 hours of treatment [146]. For diagnosis of complicating factors in pregnant women, US or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus [146].

3.6.2 **Recommendations for the diagnostic evaluation of uncomplicated pyelonephritis**

Recommendations	LE	GR
Perform urinalysis (e.g. using a dipstick method), including the assessment of white and red	4	A*
blood cells and nitrite, for routine diagnosis.		
Perform urine culture and antimicrobial susceptibility testing in patients with pyelonephritis.	4	A*
Perform ultrasound of the upper urinary tract to exclude obstructive pyelonephritis.	4	A*
Additional imaging investigations, such as an unenhanced helical computed tomography	4	A*
should be done if the patient remains febrile after 72 hours of treatment or in patients with		
suspected complications e.g. sepsis.		

*Upgraded based on panel consensus.

3.6.3 Disease management

3.6.3.1 Outpatient treatment

Fluoroquinolones and cephalosporines are the only microbial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis. However, oral cephalosporines achieve significantly lower concentrations than intravenous cephalosporines. Local fluoroquinolone resistance should be < 10%. Other agents such as nitrofurantoin, fosfomycin, and pivmecillinam should be avoided because these agents do not achieve adequate renal tissue levels [147]. In the setting of fluoroquinolone hypersensitivity or known resistance, other acceptable choices include trimethoprim-sulfamethoxazole (160/800 mg) or an oral beta-lactam, if the uropathogen is known to be susceptible. If such agents are used in the absence of antimicrobial susceptibility results, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered.

3.6.3.2 Inpatient treatment

Patients with uncomplicated pyelonephritis requiring hospitalisation should be treated initially with an intravenous antimicrobial regimen such as a fluoroquinolone, an aminoglycoside (with or without ampicillin), an extended-spectrum cephalosporin, an extended-spectrum penicillin, or a carbapenem [148]. The choice between these agents should be based on local resistance patterns and optimised on the basis of drug susceptibility results. In patients presenting with signs of urosepsis empiric antimicrobial coverage for extended-spectrum beta-lactamases (ESBL)-producing organisms is warranted [149]. Patients initially treated with parenteral therapy who improve clinically and can tolerate oral fluids may transition to oral antimicrobial therapy [150].

3.6.3.2.1 Recommendations for empirical oral antimicrobial therapy in uncomplicated pyelonephritis

Recommendations						
Antimicrobial	Daily dose	Duration of	LE	GR	Comments	
		therapy				
Ciprofloxacin	500-750 mg	7-10 days	1b	В	Fluoroquinolone resistance should be	
	b.i.d				less than 10 percent.	
Levofloxacin	750 mg q.d	5 days	1b	В		
Trimethoprim	160/800 mg b.i.d	7-14 days	1b	В	If such agents are used empirically,	
sulphamethoxazol					an initial intravenous dose of a long-	
Cefpodoxime	200 mg b.i.d	10 days	4	B*	acting parenteral antimicrobial (e.g.	
Ceftibuten	400 mg q.d	10 days	4	B*	ceftriaxone) should be administered.	

*Upgraded based on panel consensus.

b.i.d = twice daily; q.d = every day.

3.6.3.2.2 Recommendations for empirical parenteral antimicrobial therapy in uncomplicated pyelonephritis

Recommendations				
Antimicrobials	Daily dose	LE	GR	Comments
Ciprofloxacin	400 mg b.i.d	1b	В	
Levofloxacin	750 mg q.d	1b	В	
Cefotaxime	2 g t.i.d	2	A*	Not studied as monotherapy in acute
Ceftazidime	1-2 g t.i.d	2	A*	uncomplicated pyelonephritis.
Co-amoxiclav	1.5 g t.i.d	2	С	Not studied as monotherapy in acute uncomplicated pyelonephritis. Mainly for Gram- positive pathogens.
Ceftriaxone	1-2 g q.d	1b	A*	Lower dose studied, but higher dose
Cefepime	1-2 g b.i.d	1b	В	recommended. Same protocol for acute
Piperacillin/tazobactam	2.5-4.5 g t.i.d	1b	A*	uncomplicated pyelonephritis and complicated UTI (stratification not always possible).
Ceftolozane/tazobactam	1.5 g t.i.d	1b	В	
Ceftazidime/avibactam	2.5 g t.i.d	1b	В	
Gentamicin	5 mg/kg q.d	1b	В	Not studied as monotherapy in acute
Amikacin	15 mg/kg q.d	1b	В	uncomplicated pyelonephritis.
Ertapenem	1 g q.d	1b	В	Same protocol for acute uncomplicated
Imipenem/cilastatin	0.5/0.5 g t.i.d	1b	В	pyelonephritis and complicated UTI (stratification
Meropenem	1 g t.i.d	2	В	not always possible).
Doripenem	0.5 g t.i.d	1b	В	

* Upgraded based on panel consensus.

b.i.d = twice daily; *t.i.d* = three times daily; *q.d* = every day.

In pregnant women with pyelonephritis, outpatient management with appropriate antimicrobials may also be considered, provided symptoms are mild and close follow-up is feasible [151, 152]. In more severe cases of pyelonephritis, hospitalisation and supportive care are usually required. After clinical improvement parenteral therapy can also be switched to oral therapy for a total treatment duration of seven to ten days. In men with febrile UTI, pyelonephritis, or recurrent infection, or whenever a complicating factor is suspected a minimum treatment duration of two weeks is recommended, preferably with a fluoroquinolone since prostatic involvement is frequent [153].

3.6.4 **Follow-up**

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated, except in pregnant women, if asymptomatic bacteriuria is an issue (see section 3.3.6.3).

3.7 Complicated UTIs

3.7.1 Introduction

A complicated UTI (cUTI) occurs in an individual in whom factors related to the host (e.g. underlying diabetes or immunosuppression) or specific anatomical or functional abnormalities related to the urinary tract (e.g. obstruction, incomplete voiding due to detrusor muscle dysfunction) are believed to result in an infection that will be more difficult to eradicate than an uncomplicated infection [154-156]. The underlying factors that are generally accepted to result in a cUTIs are outlined in Table 2. The designation of cUTI encompasses a wide variety of underlying conditions that result in a remarkably heterogeneous patient population. Therefore, it is readily apparent that a universal approach to the evaluation and treatment of cUTIs is not sufficient, although there are general principles of management that can be applied to the majority of patients with cUTIs. The following recommendations are based on the Stichting Werkgroep Antibioticabeleid (SWAB) Guidelines from the Dutch Working Party on Antibiotic Policy [157].

Table 2: Factors associated with complicated UTIs [154-156]

Obstruction at any site in the urinary tract	UTI in males
Foreign body	Pregnancy
Incomplete voiding	Diabetes
Vesicoureteral reflux	Immunosuppression
Recent history of instrumentation	Healthcare-associated infections

3.7.2 Diagnostic evaluation

3.7.2.1 Clinical presentation

A cUTI is associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever), although in some clinical situations the symptoms may be atypical for example, in neuropathic bladder disturbances or catheter-associated UTI (CA-UTI). Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a post-operative CA-UTI, which might disappear spontaneously as soon as the catheter is removed. Clinicians must also recognise that symptoms, especially lower urinary tract symptoms (LUTS), are not only caused by UTIs but also by other urological disorders, such as, for example, benign prostatic hyperplasia and autonomic dysfunction in patients with spinal lesions and neurogenic bladders. Concomitant medical conditions, such as diabetes mellitus and renal failure, which can be related to urological abnormalities, are often also present in a cUTI.

3.7.2.2 Urine culture

Laboratory urine culture is the recommended method to determine the presence or absence of clinically significant bacteriuria in patients suspected of having a cUTI.

3.7.3 Microbiology (spectrum and antimicrobial resistance)

A broad range of microorganisms cause cUTIs. The spectrum is much larger than in uncomplicated UTIs and the bacteria are more likely to be resistant (especially in treatment-related cUTI) than those isolated in uncomplicated UTIs [158, 159]. *E. coli, Proteus spp., Klebsiella spp., Pseudomonas spp., Serratia spp.* and *Enterococcus spp.* are the most common strains found in cultures. Enterobacteriaceae predominate (60-75%), with *E. coli* as the most common pathogen; particularly if the UTI is a first infection. Otherwise, the bacterial spectrum may vary over time and from one hospital to another [160].

3.7.4 General principles of cUTI treatment

Appropriate management of the urological abnormality or the underlying complicating factor is mandatory. Optimal antimicrobial therapy for cUTI depends on the severity of illness at presentation, as well as local resistance patterns and specific host factors (such as allergies). In addition, urine culture and susceptibility testing should be performed, and initial empirical therapy should be tailored and followed by (oral) administration of an appropriate antimicrobial agent on the basis of the isolated uropathogen.

3.7.4.1 Choice of antimicrobials

In the recently updated IDSA guidelines for the treatment of uncomplicated UTI, it is recommended that the resistance percentages of causative micro-organisms must be < 20% to consider an agent suitable for empirical treatment of a lower UTI and must be < 10% for treatment of an upper UTI. Considering the current resistance percentages of amoxicillin, co-amoxiclav, trimethoprim and trimethoprim-sulphamethoxazole, it can be concluded that these agents are not suitable for the empirical treatment of pyelonephritis in a normal host and, therefore, also not for treatment of all cUTIs [161]. The same applies to ciprofloxacin and other fluoroquinolones in urological patients [161].

Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen, such as an aminoglycoside with or without amoxicillin or a second or third generation cephalosporin or an extended-spectrum penicillin with or without an aminoglycoside [157]. The choice between these agents should be based on local resistance data, and the regimen should be tailored on the basis of susceptibility results [147]. These recommendations are not only suitable for pyelonephritis but for all other cUTIs.

In view of the high degree of resistance, particularly among patients admitted to the department of urology, fluoroquinolones are not automatically suitable as empirical antimicrobial therapy, especially when the patient has used ciprofloxacin in the last six months [162]. Fluoroquinolones can only be recommended as empirical treatment when the patient is not seriously ill and it is considered safe to start initial oral treatment or if the patient has had an anaphylactic reaction to beta-lactam antimicrobials.

3.7.4.2 Duration of antimicrobial therapy

Treatment for seven to fourteen days is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality [7].

3.7.5 **Recommendations for the treatment of complicated UTIs.**

Recommendations	LE	GR		
Do not use amoxicillin, co-amoxiclav, trimethoprim and trimethoprim-sulphamethoxazole for	2	А		
empirical treatment of complicated UTI.				
Use the combination of:	2	A		
amoxicillin plus an aminoglycoside;				
a second generation cephalosporin plus an aminoglycoside;				
• a third generation cephalosporin intravenously as empirical treatment of complicated UTI				
with systemic symptoms.				
Only use ciprofloxacin provided that the local resistance percentages are < 10% when;	2	A		
• the entire treatment is given orally;				
patients do not require hospitalisation;				
patient has an anaphylaxis for beta-lactam antimicrobials.				
Do not use ciprofloxacin and other fluoroquinolones for the empirical treatment of complicated	2	A		
UTI in patients from the urology department or when patients have used fluoroquinolones in				
the last six months.				
Use an initial one-time intravenous dose of a long-acting antimicrobial, such as a third	2	A		
generation cephalosporin or an aminoglycoside if the prevalence of fluoroquinolone resistance				
is thought to be > 10% and resistance data are pending.				
If the prevalence of fluoroquinolone resistance is thought to be > 10% and the patient has	2	A		
contra indications for third generation cephalosporins or an aminoglycoside, ciprofloxacin can				
be prescribed as an empirical treatment in women with uncomplicated pyelonephritis.				
In the event of hypersensitivity to penicillin, a third generation cephalosporin can still be	2	A		
prescribed, with the exception of systemic anaphylaxis in the past.				
In patients with a UTI with systemic symptoms, empirical treatment should cover ESBL in the	2	A		
initial treatment only in patients who are colonised with ESBL-producing micro-organisms. The				
resistance pattern of the ESBL strain should guide empirical therapy.				

ESBL = Extended-spectrum beta-lactamase.

3.8 Catheter-associated UTIs

3.8.1 Introduction

Catheter-associated UTI refers to UTIs occurring in a person whose urinary tract is currently catheterised or has been catheterised within the past 48 hours. The urinary catheter literature is problematic as many published studies use the term CA-bacteriuria without providing information on what proportion are CA-ABU and CA-UTI, and some studies use the term CA-UTI when referring to CA-ABU or CA-bacteriuria [158]. The following recommendations are based on the Stichting Werkgroep Antibioticabeleid (SWAB) Guidelines from the Dutch Working Party on Antibiotic Policy [157] as well as the IDSA Guidelines [158].

3.8.2 Epidemiology, aetiology and pathophysiology

Catheter-associated UTIs are the leading cause of secondary health care-associated bacteraemia. Approximately 20% of hospital-acquired bacteraemias arise from the urinary tract, and the mortality associated with this condition is approximately 10% [163]. The incidence of bacteriuria associated with indwelling catheterisation is 3-8% per day [164-168]. The duration of catheterisation is presumable the most important risk factor for the development of a CA-UTI [169, 170]. Urinary catheterisation perturbs host defence mechanisms and provides easier access of uropathogens to the bladder. Indwelling urinary catheters facilitate colonisation with uropathogens by providing a surface for the attachment of host cell binding receptors recognised by bacterial adhesins, thus enhancing microbial adhesion. In addition, the uroepithelial mucosa is disrupted, exposing new binding sites for bacterial adhesins, and residual urine in the bladder is increased through pooling below the catheter bulb [171]. Catheter-associated UTIs are often polymicrobial and caused by multiple-drug resistant uropathogens.

3.8.3 Diagnostic evaluation

3.8.3.1 Clinical diagnosis

Signs and symptoms compatible with CA-UTI include new onset or worsening of fever, rigors, altered mental

status, malaise, or lethargy with no other identified cause, flank pain, costovertebral angle tenderness, acute haematuria, pelvic discomfort and in those whose catheters have been removed dysuria, urgent or frequent urination and suprapubic pain or tenderness [157]. In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI [157, 158].

3.8.3.2 Laboratory diagnosis

Microbiologically CA-UTI is defined by microbial growth of $\ge 10^3$ cfu/mL of one or more bacterial species in a single catheter urine specimen or in a midstream voided urine specimen from a patient whose urethral, suprapubic, or condom catheter has been removed within the previous 48 hours. In catheterised patients, pyuria is not diagnostic for CA-UTI. The presence, absence, or degree of pyuria should not be used to differentiate CA-ABU from CA-UTI. Pyuria accompanying CA-ABU should not be interpreted as an indication for antimicrobial treatment. The absence of pyuria in a symptomatic patient suggests a diagnosis other than CA-UTI [158].

3.8.3.3 Recommendations for diagnostic evaluation of CA-UTI

Recommendations	LE	GR	
Do not carry out routine urine culture in an asymptomatic catheterised patients.	1a	А	
Do not use pyuria as an indicator for catheter-associated UTI.	2	А	
Do not use the presence, absence, or degree of pyuria to differentiate catheter-associated			
asymptomatic bacteriuria from catheter-associated UTI.			
Do not use the presence or absence of odorous or cloudy urine alone to differentiate catheter-	3	С	
associated asymptomatic bacteriuria from catheter-associated UTI.			

3.8.4 Disease management

A urine specimen for culture should be obtained prior to initiating antimicrobial therapy for presumed CA-UTI due to the wide spectrum of potential infecting organisms and the increased likelihood of antimicrobial resistance. The urine culture should be obtained from the freshly placed catheter prior to the initiation of antimicrobial therapy [158].

Seven days is the recommended duration of antimicrobial treatment for patients with CA-UTI who have prompt resolution of symptoms, and two to fourteen days of treatment is recommended for those with a delayed response, regardless of whether the patient remains catheterised or not [158]. A five-day regimen of levofloxacin may be considered in patients with CA-UTI who are not severely ill. Data are insufficient to make such a recommendation about other fluoroquinolones.

A three-day antimicrobial regimen may be considered for women aged \leq 65 years who develop CA-UTI without upper urinary tract symptoms after an indwelling catheter has been removed. If an indwelling catheter has been in place for twelve weeks at the onset of CA-UTI and is still indicated, the catheter should be replaced to hasten resolution of symptoms and to reduce the risk of subsequent CA-bacteriuria and CA-UTI. If use of the catheter can be discontinued, a culture of a voided midstream urine specimen should be obtained prior to the initiation of antimicrobial therapy to help guide treatment [158].

3.8.4.1 Recommendations for disease management and prevention of CA-UTI

Becommendations	LE	GR
Take a urine culture prior to initiating antimicrobial therapy in catheterised patients in whom the catheter has been removed.	3	A*
Do not treat catheter-associated asymptomatic bacteriuria in general.	1a	А
Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract	1a	А
interventions (e.g. transurethral resection of the prostate).		
Replace or remove the indwelling catheter before starting antimicrobial therapy.	4	B*
Do not apply topical antiseptics or antimicrobials to the catheter, urethra or meatus.	1a	А
Do not use prophylactic antimicrobials to prevent catheter-associated UTIs.	1a	А
The duration of catheterisation should be minimal.	2a	В
Remove an indwelling catheter after non-urological operation within the same day.	1b	В
Change long-term indwelling catheters at intervals adapted to the individual patient.	3	С

* Upgraded based on panel consensus.

3.8.5 Follow-up

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated.

3.9 Urosepsis

3.9.1 Introduction

Patients with urosepsis should be diagnosed at an early stage, especially in the case of a cUTI. Systemic inflammatory response syndrome (SIRS), characterised by fever or hypothermia, hyperleukocytosis or leukopenia, tachycardia and tachypnoea, is recognised as the first event in a cascade leading to multi-organ failure (Figure 2). Mortality is considerably increased the more severe the sepsis is.

The treatment of urosepsis involves adequate life-supporting care, appropriate and prompt antimicrobial therapy, adjunctive measures and the optimal management of urinary tract disorders [172]. The decompression of any obstruction and drainage of larger infectious abscess in the urinary tract is essential as first-line focus control [172]. Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists.

Urosepsis is seen in both community-acquired and healthcare associated infections. Nosocomial urosepsis may be reduced by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urethral catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily aseptic techniques to avoid cross-infection.

Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation, presence of symptoms of organ dysfunction and persistent hypotension associated with tissue anoxia.

3.9.2 Epidemiology, aetiology and pathophysiology

Urinary tract infections can manifest from bacteriuria with limited clinical symptoms to sepsis or severe sepsis, depending on localised and potential systemic extension. It is important to note that a patient can move from an almost harmless state to severe sepsis in a very short time.

Mortality rates associated with severe sepsis vary depending on the organ source [173] with urinary tract sepsis generally having a lower mortality than that from other sources [174]. Sepsis is more common in men than in women [175]. In recent years, the overall incidence of sepsis arising from all sources has increased by 8.7% per year [173], but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% from 1995 to 2000) [176]. Although sepsis due to fungal organisms from some sites has increased and Gram-positive bacteria have become the predominant pathogen overall, Gram-negative bacteria remain predominant in urosepsis [177, 178].

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response. Patients who are more likely to develop urosepsis include elderly patients, diabetics, immunosuppressed patients, such as transplant recipients and patients receiving cancer chemotherapy or corticosteroids. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract.

3.9.3 Diagnostic evaluation

Clinical diagnosis of a UTI is based on symptoms, physical examination, sonographic and radiological features, and laboratory data, such as bacteriuria and leukocyturia. Table 3 details the current criteria for the diagnosis of sepsis and septic shock.

Disorder	Definition
Systematic inflammatory response syndrome (SIRS)	 Response to a wide variety of clinical insults, which can be infectious, as in sepsis but may also be non-infectious in aetiology (e.g. burns, or pancreatitis). This systemic response is manifested by two or more of the following criteria: temperature > 38°C or < 36°C; heart rate > 90 bpm; respiratory rate > 20 breaths/min or PaCO₂ < 32 mmHg (< 4.3 kPa); white blood cell count > 12,000 cells/mm³ or < 4,000 cells/mm³ or > 10% immature (band) forms.
Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection. For clinical application, organ dysfunction can be represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more. For rapid identification a quickSOFA (qSOFA) score was developed: respiratory rate of 22/min or greater, altered mentation, or systolic blood pressure of 100 mmHg or less.
Septic shock	Septic shock should be defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. Patients with septic shock can be clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mmHg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

Table 3. Definition and criteria of sepsis and septic shock [179-181]

3.9.4 **Physiology and biochemical markers**

E. coli remains the most prevalent microorganism. In several countries, bacterial strains can be resistant or multi-resistant and therefore difficult to treat [178]. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection.

3.9.4.1 Cytokines as markers of the septic response

Cytokines are involved in the pathogenesis of sepsis syndrome [174]. They are molecules that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood [174].

3.9.4.2 Procalcitonin and mid-regional proadrenomedulline

Procalcitonin is the inactive pro-peptide of calcitonin. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels rise [182]. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show only a moderate or no increase. Mid-regional proadrenomedulline is another sepsis marker. Mid-regional proadrenomedullin has been shown to play a decisive role in the induction of hyperdynamic circulation during the early stages of sepsis and progression to septic shock [183]. Procalcitonin monitoring may be useful in patients likely to develop sepsis and to differentiate from a severe inflammatory status not due to bacterial infection [182, 184]. In addition serum lactate is a marker of organ dysfunction and is associated with mortality in sepsis [185]. Serum lactate should therefore also be monitored in patients with severe infections.

3.9.5 Disease management

3.9.5.1 Prevention

Septic shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Urosepsis treatment requires a combination of treatment including treatment of the cause (obstruction of the urinary tract), adequate life-support care, and appropriate antimicrobial therapy [174]. In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

3.9.5.1.1 Preventive measures of proven or probable efficacy

The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections [186, 187] they include:

- Isolation of all patients infected with multi-resistant organisms to avoid cross-infection.
- Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay, it is well known that long inpatient periods before surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting [188]. Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
- Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

3.9.5.1.2 Appropriate peri-operative antimicrobial prophylaxis

For appropriate peri-operative antimicrobial prophylaxis see section 3.15. The potential side-effects of antibiotics must be considered before their administration in a prophylactic regimen.

3.9.5.2 Treatment

During the first six hours of resuscitation, the goals of initial resuscitation of sepsis-induced hypoperfusion should include all of the following:

- central venous pressure (CVP) 8-12 mmHg;
- mean arterial pressure (MAP) 65-90 mmHg;
- central venous oxygen (CVO2) > 70%;
- haematocrit (HKT) > 30 %;
- urine output > 0.5 mL/kg/hr.

Early goal-directed resuscitation was initially shown to improve survival for emergency department patients presenting with septic shock in a randomised, controlled, single-centre study [189]. However, recent follow up studies in an improved emergency medicine background have not achieved positive effects with this strategy [190-192].

3.9.5.2.1 Antimicrobial therapy

Initial empiric antimicrobial therapy should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available [172]. The dosage of the antimicrobial substances is of paramount importance in patients with sepsis syndrome and should generally be high, with the exception of patients in renal failure [172]. Antimicrobials must be administered no later than one hour after clinical assumption of sepsis (Figure 2) [172].

3.9.5.2.1.1 Recommendations fo	r parenteral antimicro	obial therapy of urosepsis
--------------------------------	------------------------	----------------------------

Recommendations						
Antimicrobials	Daily dose	LE	GR	Comments		
Cefotaxime	2 g t.i.d	2	A*	Not studied as monotherapy in acute		
Ceftazidime	1-2 g t.i.d	2	A*	uncomplicated pyelonephritis.		
Ceftriaxone	1-2 g q.d	1b	A*	Lower dose studied, but higher dose		
Cefepime	1-2 g b.i.d	1b	В	recommended. Same protocol for acute		
Piperacillin/tazobactam	2.5-4.5 g t.i.d	1b	A*	uncomplicated pyelonephritis and complicated		
				UTI (stratification not always possible).		
Ceftolozane/tazobactam	1.5 g t.i.d	1b	В			
Ceftazidime/avibactam	2.5 g t.i.d	1b	В			
Gentamicin	5 mg/kg q.d	1b	В	Not studied as monotherapy in acute		
Amikacin	15 mg/kg q.d	1b	В	uncomplicated pyelonephritis.		
Ertapenem	1 g q.d	1b	В	Same protocol for acute uncomplicated		
Imipenem/cilastatin	0.5/0.5 g t.i.d	1b	В	pyelonephritis and complicated UTI (stratification		
Meropenem	1 g t.i.d	2	В	not always possible).		
Doripenem	0.5 g t.i.d	1b	В			

* Upgraded based on panel consensus.

b.i.d = twice daily; *t.i.d* = three times daily; *q.d* = every day.

3.9.5.2.2 Source control

Drainage of any obstruction in the urinary tract and removal of foreign bodies, such as urinary catheters or stones, should lead to resolution of symptoms and recovery. These are key components of the strategy. This condition is an absolute emergency.

3.9.5.2.3 Adjunctive measures

The most important adjunctive measures in the management of sepsis are the following [172]:

- fluid therapy with crystalloids, or albumin, if crystalloids are not adequately increasing blood pressure;
- as vasopressors norepinephrine should be used primarily, dobutamine in myocardial dysfunction;
- hydrocortisone should be given only if fluid and vasopressors do not achieve a mean arterial pressure of
 ≥ 65 mmHg;
- blood products should be given to target a haemoglobin level of 7-9 g/dL;
- mechanical ventilation should be applied with a tidal volume 6 ml/kg and plateau pressure ≤ 30 cm H₂O and a high positive end-expiratory pressure;
- sedation should be given minimally, neuromuscular blocking agents should be avoided;
- glucose levels should be target at ≤ 180 mg/dL;
- deep vein thrombosis prevention should be given with low-molecular weight heparin subcutaneously;
- stress ulcer prophylaxis should be applied in patients at risk, using protone pump inhibitors;
- enteral nutrition should be started early (< 48 hours).

In conclusion, sepsis syndrome in urology remains a severe situation with an considerable mortality rate. A recent campaign, 'Surviving Sepsis Guidelines', aims to reduce mortality by 25% in the next years [172, 193]. Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antimicrobial treatment provide the best conditions for improving patient survival. The prevention of sepsis syndrome is dependent on good practice to avoid nosocomial infections and using antimicrobial prophylaxis and therapy in a prudent and well-accepted manner.

Figure 2: Clinical algorithm for the management of urosepsis

3.10 Urethritis

3.10.1 Introduction

Inflammation of the urethra presents usually with symptoms of the LUT and must be distinguished from other infections of the LUT. The following recommendations are based on a review of several European national guidelines and are aligned with the CDC's guidelines on sexual transmitted diseases (STDs) [194-197].

3.10.2 Epidemiology, aetiology and pathogenesis

From a therapeutic and clinical point of view, *gonorrhoeal urethritis* (GU) must be differentiated from nongonococcal urethritis (NGU). Infection is spread by sexual contact. Causative pathogens include *Neisseria* gonorrhoeae (NG), *Chlamydia trachomatis* (CT), *Mycoplasma genitalium* (MG), *Trichomonas vaginalis* (TV), and *Ureaplasma urealyticum* (UU) [198-203]. In a study of 367 patients with NGU isolated causative pathogens were: CT in 22.3%, MG in 12.5%, TV in 2.5%, and UU in 24.0%, with multiple pathogens detected in 9.5% and no aetiology in 29.2% [198]. There is limited evidence to support the role of *Mycoplasma hominis* in urethritis [204, 205].

Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (*N. gonorrhoeae* and *C. trachomatis*) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women [206-208].

Mucopurulent or purulent discharge, alguria, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

3.10.3 Diagnostic evaluation

A Gram stain of urethral discharge or a urethral smear that shows more than five leukocytes per high power

field (× 1,000) and eventually, gonococci located intracellularly as Gram-negative diplococci, indicate pyogenic urethritis [209]. Laboratories should use validated nucleic acid amplification tests (NAATs) to detect chlamydia and gonorrhoea, in first void urine samples, as they are better than any of the other tests available for the diagnosis of chlamydial and gonococcal infections [210]. *N. gonorrhoeae* and chlamydia cultures are mainly to evaluate treatment failures and monitor developing resistance to current treatment.

In all patients with urethritis, and when sexual transmission is suspected, the aim should be to identify the pathogenic organisms. *Trichomonas* spp. can usually be identified microscopically [208].

3.10.3.1 Recommendations for the diagnostic evaluation of urethritis

Recommendations	LE	GR
Use a gram stain of urethral discharge or a urethral smear to preliminarily diagnosis pyogenic	3	В
urethritis.		
Use a validated nucleic acid amplification tests to diagnosis chlamydial and gonococcal	3	В
infections.		

3.10.4 **Disease management**

Broad spectrum empirical antibiotic therapy may be started on presentation followed by antibiotic treatment refinement according to the results of microbiological investigations.

Pathogen	Antimicrobial	Dosage & Duration of therapy	LE	GR	Alternative regimens
Gonococcal	Ceftriaxone	1 g i.m., SD	1a	А	Cefixime 400 mg p.o., SD
Infection	Azithromycin	1-1.5 g p.o., SD			Or
	Cefixime	800 mg p.o., SD			Azithromycin 1-1.5 g p.o., SD
Non-Gonococcal infection (non- identified pathogen)	Doxycycline	100 mg b.i.d, p.o., 7-10 days	1b	A	Azithromycin 0.5 g p.o., day 1, 250 mg p.o., days 2-5
Chlamydia trachomatis	Azithromycin	1.0-1.5 g p.o., SD	1b	A	Doxycycline 100 mg b.i.d, p.o., for 7 days
Mycoplasma genitalium	Azithromycin	0.5 g p.o., day 1, 250 mg p.o., day 2-5	2a	В	Moxifloxacin 400 mg q.d., 5 days however, because of reported failures, some experts recommend 10 -14 days
Ureaplasma urealiticum	Doxycycline	100 mg b.i.d, p.o., 7 days	1b	A	Azithromycin 1.0-1.5 g p.o., single dose Or Clarithromycin 500 mg b.i.d, 7 days (resistance against macrolides is possible)
Trichomonas vaginalis	Metronidazole	2 g p.o., SD	1a	A	In case of persistence 4 g daily for 3-5 days

0 1 0 1 1	D / // /		e	1011	0401
3.10.4.1	Recommendations for a	intimicrobial therapy	of Urethritis	211,	212

SD = single dose; b.i.d = twice daily; q.d = everyday; p.o. = orally, i.m. = intramuscular.

3.10.5 **Follow-up**

Patients should be followed-up for control of eradication or if symptoms persist or recur after completion of therapy. Patients should be instructed to abstain from sexual intercourse for seven days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Reporting and source tracing should be done in accordance with national guidelines and in co-operation with specialists in venereology, whenever required. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV.

3.11 Bacterial Prostatitis

3.11.1 Introduction

Bacterial prostatitis is a clinical condition caused by bacterial infection of the prostate gland. It is

recommended that urologists use the classification suggested by the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis, with confirmed or suspected infection, is distinguished from chronic pelvic pain syndrome (CPPS) (Table 4) [213-215].

Туре	Name and description
1	Acute bacterial prostatitis
II	Chronic bacterial prostatitis
III	Chronic abacterial prostatitis – chronic pelvic pain syndrome
IIIA	Inflammatory chronic pelvic pain syndrome (white cells in semen/expressed prostatic
	secretion/voided bladder urine 3)
IIIB	Non-inflammatory chronic pelvic pain syndrome (no white cells in semen/expressed
	prostatic secretion/voided bladder urine 3)
IV	Asymptomatic inflammatory prostatitis (histological prostatitis)

Table 4: Classification of prostatitis and CPPS according to NIDDK/NIH [213-215]

3.11.2 Epidemiology, aetiology and pathogenesis

A causative pathogen is detected by routine methods in only 5-10% of cases [216], antimicrobial therapy in these patients therefore, has a rational basis [217, 218]. The remainder of patients are treated empirically with numerous medical and physical modalities. However, recent improvement in classification and application of modern methods, including molecular biology, should allow proper systematisation of treatment [218, 219]. Enterobacteriaceae, especially *E. coli*, are the predominant pathogens in acute bacterial prostatitis [220]. In chronic bacterial prostatitis, the spectrum of strains is wider [218]. In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis, Candida sp.* and rare pathogens, such as *Coccidioides immitis, Blastomyces dermatitidis*, and *Histoplasma capsulatum* [221]. The significance of intracellular bacteria, such as *C. trachomatis*, is uncertain [222] however, two studies have highlighted its role as a causative pathogen in chronic bacterial prostatitis [223, 224].

3.11.3 Diagnostic evaluation

3.11.3.1 History and symptoms

According to the duration of symptoms, bacterial prostatitis is described as either acute or chronic, the latter being defined by symptoms that persist for at least three months [225-227]. The predominant symptoms are pain at various locations (Table 5) and LUTS such as a frequent need to urinate, difficulty urinating e.g. weak stream, straining and pain on urination, or that increases during urination [213-215]. Chronic bacterial prostatitis is the most frequent cause of rUTI in men [228].

Site of pain	Percentage of patients
Prostate/perineum	46%
Scrotum and/or testes	39%
Penis	6%
Urinary bladder	6%
Lower back	2%

Table 5: Localisation of pain in patients with prostatitis like symptoms [215]

3.11.3.2 Symptom questionnaires

Symptoms appear to have a strong basis for use as a classification parameter in bacterial prostatitis [229]. Prostatitis symptom questionnaires have therefore been developed for the quantification of symptoms [229, 230]. They include the Chronic Prostatitis Symptom Index (CPSI), which was recently developed by the International Prostatitis Collaborative Network (IPCN), initiated by the NIH [231]. The questionnaire contains four questions regarding pain or discomfort, two regarding urination, and three related to quality of life.

3.11.4 Clinical findings

In acute prostatitis, the prostate may be swollen and tender on DRE. Prostatic massage is contraindicated. Otherwise, the prostate is usually normal on palpation. In case of lasting symptoms ("chronic prostatitis" symptoms) CPPS as well as other urogenital and ano-rectal disorders must be taken into consideration. Symptoms of chronic prostatitis or CPPS can mask prostate tuberculosis. Pyospermia and haematospermia in

men in endemic regions or with a history of tuberculosis should prompt investigation for urogenital tuberculosis [218].

3.11.4.1 Urine cultures and expressed prostatic secretion

The most important investigation in the evaluation of a patient with acute prostatitis is MSU culture [232]. If the patient presents with clinical signs suggestive of blood-stream infection, a blood culture should be taken following local protocols. In chronic bacterial prostatitis, quantitative bacteriological localisation cultures and microscopy of the segmented urine and of expressed prostatic secretion (EPS), as described by Meares and Stamey [217] are important investigations.

3.11.4.2 Prostate biopsy

Perineal biopsies cannot be recommended as routine work-up and should be reserved only for research purposes. Transrectal prostate biopsy is not advisable in bacterial prostatitis [232].

3.11.4.3 Other tests

Transrectal ultrasound (TRUS) may reveal intraprostatic abscesses, calcification in the prostate, and dilatation of the seminal vesicles but is unreliable and cannot be used as a diagnostic tool in prostatitis [233].

3.11.4.4 Additional investigations

3.11.4.4.1 Ejaculate analysis

An analysis of the ejaculate is not recommended for microbiological investigation due to the low sensitivity and specificity compared to the two or three-glass tests [232]. Ejaculate analysis is however frequently involved as part of the investigation of a generalised male accessory gland infection. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy.

3.11.4.4.2 Prostate specific antigen

Prostate specific antigen (PSA) is often increased in acute bacterial prostatitis and other urogenital infections. If a patient has elevated PSA and evidence of prostatic inflammation, serum PSA will normalise after antimicrobial treatment of four weeks in about 50% of patients [234]. A delay of at least three months should be allowed before it can be assumed that a stable level of PSA has been reached. Measurement of free and total PSA adds no practical diagnostic information in prostatitis [235].

3.11.5 Recommendations for the diagnostic evaluation of bacterial prostatitis

Recommendations	LE	GR	
Perform digital rectal examination to assess the condition of the prostate.	4	A*	
Take a mid-stream urine culture in patients with acute prostatitis-related symptoms for	3	A*	
diagnosis and targeted treatment planning.			
Perform the Meares and Stamey four-glass test in patients with chronic bacterial prostatitis.	2b	В	
Accurate microbiological evaluation for atypical pathogens such as Chlamydia trachomatis or			
Mycoplasmata is recommended in patients with chronic bacterial prostatitis.			
Perform transrectal ultrasound only in selected cases to rule out the presence of prostatic			
abscess, calcification in the prostate and dilatation of the seminal vesicles.			
Ejaculate analysis and prostate specific antigen measurement should not be performed as	3	В	
routine, due to the high number of false positive results.			

*Upgraded based on panel consensus.

3.11.6 Disease management

3.11.6.1 Antimicrobials

Antimicrobials are life-saving in acute bacterial prostatitis and recommended in chronic bacterial prostatitis.

Acute bacterial prostatitis is a serious infection with fever and intense localised and general pain. Parenteral administration of high doses of bactericidal antimicrobials, such as a broad-spectrum penicillin, a third-generation cephalosporin or a fluoroquinolone, is recommended [232]. For initial therapy, any of these antimicrobials may be combined with an aminoglycoside [218, 232]. After defervescence and normalisation of infection parameters, oral therapy can be substituted in and continued for a total of two to four weeks [236].

Fluoroquinolones, such as ciprofloxacin and levofloxacin, are considered drugs of choice because of their favourable pharmacokinetic properties [237], their generally good safety profile, and antibacterial activity against Gram-negative pathogens, including *Pseudomonas aeruginosa*. In addition, levofloxacin is

active against Gram-positive and atypical pathogens, such as C. trachomatis and genital mycoplasmas.

The duration of antimicrobial treatment is based on clinical experience [238]. In chronic bacterial prostatitis antimicrobials should be given for four to six weeks after initial diagnosis [218, 232]. Relatively high doses are needed and oral therapy is preferred [237, 238]. If intracellular bacteria have been detected or are suspected, tetracyclines or erythromycin should be given [237, 239].

Antimicrobial	Daily dose	Duration of therapy	LE	GR	Comments
Acute febrile bac	terial prostatitis	with symptoms and fe	ever		
Levofloxacin	500 mg q.d	All parental treatment	2	В	All of these antimicrobials can be
Ciprofloxacin	500 mg b.i.d	should be given until			administered in conjunction with
Ceftriaxone	2 g q.d	defervescence			aminoglycosides e.g.
Piperacillin/	4.5 g t.i.d				Gentamicin 5 mg/kg q.d or
tazobactam					Amikiacin 15 mg/kg q.d.
Cefepime	2 g b.i.d				
Acute afebrile ba	acterial prostatit	is with symptoms or a	fter def	ervesc	ence
Levofloxacin	500 mg q.d	2-4 weeks	2	В	
Ciprofloxacin	500 mg b.i.d or	2-4 weeks			
	1000 mg p.d				
Trimethoprim	200 mg b.i.d	2-4 weeks			
Co-trimoxazole	960 mg b.id	2-4 weeks			
Doxycycline	100 mg b.i.d	10 days	2	В	Only for Chlamydia trachomatis or
					mycoplasma infections.
Chronic bacteria	l prostatitis				
Levofloxacin	500 mg q.d	4-6 weeks	3	В	
Ciprofloxacin	500 mg b.i.d or	4-6 weeks			
	1000 mg q.d				
Trimethoprim	200 mg b.i.d	4-6 weeks			
Co-trimoxazole	960 mg b.i.d	4-6 weeks			
Doxycycline	100 mg b.i.d	10 days	2	В	Only for Chlamydia trachomatis or
					mycoplasma infections.

3.11.6.2 Recommendations for the disease management of bacterial prostatitis

b.i.d = twice daily; t.i.d = three times daily; q.d = every day.

3.11.6.3 Intraprostatic injection of antimicrobials

This treatment has not been evaluated in controlled trials and should not be considered [240, 241].

3.11.6.4 Drainage and surgery

Approximately 10% of men with acute prostatitis will experience urinary retention [242] which can be managed by suprapubic, intermittent or indwelling catheterisation. Suprapubic cystostomy placement is generally recommended. The use of catheterisation without evidence of retention may increase the risk of progression to chronic prostatitis [243]. Alpha-blocker treatment has also been recommended, but clinical evidence of benefit is poor [218, 232].

In case of prostatic abscess, both drainage and conservative treatment strategies appear feasible [244]. The size may matter. In one study conservative treatment was successful if the abscess cavities were < 1 cm in diameter, while larger abscesses were better treated by single aspiration or continuous drainage [245].

3.11.7 **Follow-up**

In asymptomatic post-treatment patients routine urinalysis and/or urine culture is not mandatory. The Meares and Stamey four-glass test should be repeated in patients representing with persistent symptoms. In patients with persistent symptoms and repeated positive microbiological results for sexually transmitted infectious pathogens, microbiological screening of the patients partner(s) is recommended [218, 232].

3.12 Acute Infective Epididymitis

3.12.1 Evidence question

In men with acute epididymitis what is the best antimicrobial treatment strategy for clinical resolution and eradication of the causative pathogen?

3.12.2 Epidemiology, Aetiology and Pathophysiology

Epididymitis is a common condition with incidence ranging from 25 to 65 cases per 10,000 adult males per year and can be acute, chronic or recurrent [246]. Acute epididymitis is clinically characterised by pain, swelling and increased temperature of the epididymis, which may involve the testis and scrotal skin. It is generally caused by migration of pathogens from the urethra or bladder. Torsion of the spermatic cord (testicular torsion) is the most important differential diagnosis in boys and young men.

The predominant pathogens isolated are *C. trachomatis*, Enterobacteriaceae (typically *E. coli*) and *N. gonorrhoeae* [247]. Men who have anal intercourse and those with abnormalities of the urinary tract resulting in bacteriuria are at higher risk of epididymitis caused by Enterobacteriaceae. The mumps virus should be considered if there are viral prodromal symptoms and salivary gland enlargement. Tuberculous epididymitis may occur in high-risk groups such as men with immunodeficiency and those from high prevalence countries, it frequently results in a discharging scrotal sinus. *Brucella* or *Candida* species are rare possible pathogens.

3.12.3 Diagnostic Evaluation

Culture of a mid-stream specimen of urine should be performed and any previous urine culture results should be checked. Sexually transmitted infection with *C. trachomatis* or *N. gonorrhoeae* should be detected by NAAT on first voided urine. A urethral swab or smear should be performed for Gram staining and culture if *N. gonorrhoeae* is likely. Detection of these pathogens should be reported according to local arrangements. All patients with probable STI should be advised to attend an appropriate clinic to be screened for other sexually transmitted infections. Men with Enterobacteriaceae may require investigation for lower urinary tract abnormalities. If tuberculous epididymitis is suspected, three sequential early morning urine samples should be cultured for acid-fast bacilli (AFB) and sent for screening by NAAT for *M. tuberculosis* DNA [248]. Prostate secretion, ejaculate, discharge from a draining scrotal fistula, as well as fine needle aspiration and biopsy specimens should be investigated using microscopy, AFB culture and NAAT, respectively.

3.12.4 Disease Management

Men with suspected STI should be informed of the risks to others and advised not to have sex until free of infection. Empirical antimicrobial therapy has to be chosen by consideration of the most probable pathogen and degree of penetration into the inflamed epididymis and may need to be varied according to local pathogen sensitivities and guidance. Generally, both *C. trachomatis* and Enterobacteriaceae should be covered initially and the regimen modified according to pathogen identification. Doxycycline and some specific fluoroquinolones have good clinical and microbiological cure rates in patients with suspected *C. trachomatis* and both achieve adequate levels in inflamed male genital tissues with oral dosing. Macrolide antibiotics such as azithromycin are effective against *C. trachomatis* but not tested in epididymitis. Fluoroquinolones remain effective for oral treatment of Enterobacteriaceae although resistance is increasing and local advice should be sought. Fluoroquinolones should not be considered for gonorrhoeae. Single high parenteral dose of a third generation cephalosporin is effective against *N. gonorrhoeae*; current resistance patterns and local public health recommendations should guide choice of agent.

Clinical response to antibiotics in men with severe epididymitis should be assessed after about three days and men with likely or proven STI should be assessed at fourteen days to check cure and ensure tracing and treatment of contacts according to local public health recommendations.

3.12.5 Evidence Summary

Relating to this chapter three guidelines based on systematic reviews were identified [249-251] with search dates of December 2009, March 2012 and April 2013 respectively. A structured search of the literature from January 2010 to March 2015 identified 553 titles of which 45 were selected for full text review and five were included [252-256]. Data from a large comparative case series suggested that young age and history of sexual activity are not sufficiently predictive of a sexually transmitted pathogen to guide antibiotic treatment in acute epididymitis [256].

Empiric antibiotic regimens from existing guidelines [249-251] and panel consensus:

- 1. For men with acute epididymitis at low risk of gonorrhoea (e.g. no discharge) a single agent or combination of two agents of sufficient dose and duration to eradicate *C. trachomatis* and Enterobacteriaceae should be used. Appropriate options are:
 - A. A fluoroquinolone active against *C. trachomatis* orally once daily for ten to fourteen days*
 - OR
 - B. Doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days* *plus* an antibiotic active against Enterobacteriaceae** for ten to fourteen days*

- 2. For men with likely gonorrhoeal acute epididymitis a combination regimen active against Gonococcus and *Chlamydia trachomatis* must be used such as:
 - Ceftriaxone 500 mg intramuscularly single dose plus
 Doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days*
- For non-sexually active men with acute epididymitis a single agent of sufficient dose and duration to eradicate Enterobacteriaceae should be used. Appropriate option is a fluoroquinolone by mouth once daily for ten to fourteen days*

*Depending upon pathogen identification and clinical response. ** A parenteral option will be required for men with severe infection requiring hospitalisation.

Surgical exploration may be required to drain abscesses or debride tissue. A comparative cohort study found that lack of separation of epididymis and testis on palpation and the presence of abscess on US may predict requirement for surgery following initial antibiotic treatment [252].

A cohort study found semen parameters may be impaired during epididymitis but recovered following successful treatment [255]. Comparative clinician cohort studies suggest adherence to guidelines for assessment and treatment of epididymitis is low, particularly by urologists compared to sexual health specialists [253] and by primary care physicians [254].

3.12.6 Recommendations for the treatment of acute infective epididymitis

Recommendations	LE	GR		
Obtain a mid-stream urine and first voided urine for pathogen identification.	3	A*		
Initially prescribe a single antibiotic or a combination of two antibiotics active against	3	A*		
Chlamydia trachomatis and Enterobacteriaceae in young sexually active men; in older men				
without sexual risk factors only Enterobacteriaceae have to be considered.				
If gonorrhoeal infection is likely, give single dose ceftriaxone 500 mg intramuscularly in addition				
to a course of an antibiotic active against Chlamydia trachomatis.				
Adjust antibiotic agent when pathogen has been identified and adjust duration according to				
clinical response.				
Follow national policies on reporting and tracing/treatment of contacts for sexually transmitted	3	A*		
infections.				

* Upgraded based on Panel consensus.

Figure 3: Diagnostic and treatment algorithm for adult men with acute epididymitis.

3.13 Fournier's Gangrene

3.13.1 Introduction

Fournier's gangrene is an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, peri-anal region, and external genitalia [257]. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway. Evidence regarding investigation and treatment is predominantly from case series.

3.13.2 Diagnostic evaluation

Fournier's gangrene remains rare but its incidence is increasing with an ageing population and higher prevalence of diabetes, and emergence of multi-resistant pathogens. Typically there is painful swelling of the scrotum or perineum with severe sepsis [258]. Examination shows small necrotic areas of skin with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease [259]. Risk factors include immuno-compromised patients, most commonly diabetes or malnutrition, or a recent history of catheterisation, instrumentation or perineal surgery. In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment [260, 261]. A high index of suspicion and careful examination, particularly of obese patients, is required.

3.13.2.1 Microbiology

Fournier's gangrene is typically a type 1 necrotising fasciitis that is polymicrobial in origin, including *S.aureus*, Streptococcus sp., *Klebsiella sp.*, *E. coli* and anerobes; involvement of *Clostridium* sp. is now less common [258, 260, 262]. These organisms secrete endotoxins causing tissue necrosis and severe cardiovascular impairment. Subsequent inflammatory reaction by the host contributes to multi-organ failure and death if untreated.

3.13.3 Disease management

The degree of internal necrosis is usually vastly greater than suggested by external signs, and consequently,

adequate, repeated surgical debridement is necessary to save the patient's life [263]. Disease-specific severity scoring systems do not appear superior to generic critical illness scores and are therefore not recommended for routine use [264-266]. Computed tomography or MRI can help define para-rectal involvement, suggesting the need for colostomy [267]. Consensus from case series suggests that surgical debridement should be early (< 24 hours) and complete, as delayed and/or inadequate surgery results in higher mortality [268]. Concurrent parenteral antibiotic treatment should be given that covers all causative organisms and can penetrate inflammatory tissue. This can then be refined following surgical cultures. The benefit of pooled immunoglobulin therapy and hyperbaric oxygen remains uncertain and should not be used routinely [267, 269, 270]. With aggressive early surgical and medical management, survival rates are > 70% depending upon patient group and availability of critical care [271]. Following resolution, reconstruction using skin grafts is required [272-275].

3.13.3.1 Recommendations for the disease management of Fournier's Gangrene

Recommendations	LE	GR		
Commence full, repeated, surgical debridement within 24 hours of presentation.	3	В		
Start treatment with broad-spectrum antibiotics on presentation, with subsequent refinement				
according to culture and clinical response.				
Do not use adjunctive treatments such as pooled immunoglobulin and hyperbaric oxygen,				
except in the context of clinical trials.				

* Upgraded based on panel consensus.

3.14 Detection of bacteriuria prior to urological procedures

3.14.1 Evidence question

What is the diagnostic accuracy of alternative urinary investigations compared with urine culture for the diagnosis of bacteriuria in adult patients prior to urological interventions?

3.14.2 Background

Identifying bacteriuria prior to diagnostic and therapeutic procedures aims to reduce the risk of infectious complications by controlling any pre-operative detected bacteriuria and to optimise antimicrobial coverage in conjunction with the procedure. However, the absence of bacteriuria by itself is not an assurance against infectious complications and antimicrobial prophylaxis according to section 3.15 is recommended.

The standard method, laboratory culture of an appropriate urine sample, is time consuming and logistically difficult. Alternative rapid near-patient methods such as reagent strip (dipstick) urinalysis, automated microscopy, flow cytometry, and dipslide culture have been developed but their diagnostic accuracy is uncertain.

3.14.3 Evidence summary

A systematic search of the literature to February 2015 identified 3,033 titles of which 210 were selected for full text review and 18 studies investigating diagnostic accuracy of different index tests with urine culture as the reference standard were included [276-293]. None of the studies focused on a urology patient population.

3.14.3.1 Reagents strip (dipstick) urinalysis

Sixteen studies assessed dipstick urine analysis using a variety of criteria for a positive test [276-284, 287-289]. The criterion that resulted in the best overall diagnostic accuracy was when a positive test was defined as at least one of nitrite and leucocyte esterase being detected however, low sensitivity (0.8) limits clinical usefulness, in the setting of assessment of bacteriuria, prior to urological surgery.

3.14.3.2 Automated microscopy

Two studies used automated microscopy of urine sediment following centrifugation [285, 289]. Although sensitivity was high (0.98), specificity was too low for effective use in this setting (0.59) and optimum diagnostic thresholds were not determined.

3.14.3.3 Dipslide culture

Two studies on dipslide technology using different culture media were identified [286, 293]. In one study diagnostic accuracy was high (0.98) although contaminated samples were excluded [31]. The other study showed lower accuracy, below the level required in this setting [286]. Overall, dipslide technology is currently unsuited for routine use in this setting with further studies required to determine the best combination of culture media.

3.14.3.4 Flow cytometry

No studies on this technology that met the inclusion criteria. The poor quality of available studies was confirmed in a meta-analysis [294]. In summary, laboratory urine culture remains the standard investigation to detect both the presence and absence of clinically relevant concentrations of bacteria in urine.

Recommendation	LE	GR
Laboratory urine culture is the recommended method to determine the presence or absence of	3	В
clinically significant bacteriuria in patients prior to undergoing urological interventions.		

3.15 Peri-operative antibacterial prophylaxis in urology

3.15.1 Introduction

The aim of antimicrobial prophylaxis (AMP) in urology is to prevent infectious complications resulting from diagnostic and therapeutic procedures. However, evidence for the best choice of antimicrobials and regimens is limited.

As microbial resistance is dramatically increasing, there is a strong need to change unproven paradigms. In the absence of high level evidence regarding the benefit of AMP, prior to a specific procedure, the Guideline panel recommends to individually assess its need for each case. It is important to keep in mind that AMP is only one of several measures to prevent infections and can never compensate for poor hygiene and operative technique. The CDC has presented definitions that are currently the most comprehensive, and are recommended for the evaluation of infectious complications [295]. These definitions have also been used in the Global Prevalence Study on Infections in Urology (GPIU) point prevalence studies [296].

3.15.2 Risk factors

The risk of infection varies with the type of intervention. The wide spectrum of interventions and the recent advances in minimal invasive surgery have further complicated the provision of clear-cut recommendations. Furthermore, the bacterial load, the duration and difficulty of the procedure, the surgeon's skill, and perioperative bleeding may also influence the risk of infection [295, 297, 298]. For elective urological surgery, general and urinary-tract-specific risk factors must be controlled (i.e. bacteriuria, obstruction).

Before surgery, it is essential to categorise the patients in relation to:

- their general health status according to the American Society of Anaesthesiology (ASA) score P1-P5;
- the presence of general risk factors such as older age, diabetes mellitus, impaired immune system, malnutrition, extreme weight; even though these risk factors were not proven in level one evidence studies;
- the presence of specific endogenous or exogenous risk factors such as a history of UTI or urogenital infection, indwelling catheters, bacterial burden, previous instrumentation, genetic factors;
- the type of intervention and surgical field contamination burden;
- the expected level of invasiveness, duration and technical aspects of the procedure.

3.15.3 Principles of antimicrobial prophylaxis

3.15.3.1 Timing

Overall, administration of the first dose of antimicrobial within 60 minutes before surgical incision is recommended. Administration of vancomycin and fluoroquinolones should begin within 120 minutes before surgical incision due to the prolonged infusion times required for these drugs [299, 300].

3.15.3.2 Route of administration

The preferred route of administration varies with the type of procedure, however, for a majority of procedures, intravenous administration is ideal as it produces rapid, reliable, and predictable serum and tissue concentrations [299, 300].

3.15.3.3 Duration of the regimen

For most procedures, duration of AMP has not yet been adequately addressed and rarely can a defined regimen be recommended. In principle, the duration of peri-operative prophylaxis should be minimised, ideally to a single dose.

3.15.3.4 Choice of antimicrobials

No clear-cut recommendations can be given, as there is considerable variation in Europe regarding bacterial spectra and their susceptibility to different antimicrobials. Therefore, knowledge of the local pathogen profiles, susceptibility and virulence is mandatory in establishing local AMP guidelines. It is also essential to define the

predominant pathogens for each type of procedure. When choosing an antimicrobial agent, it is necessary to consider the procedure-specific risk factors, contamination load, target organ, and the role of local inflammation.

3.15.4 Antimicrobial prophylaxis by procedure

3.15.4.1 Diagnostic procedures

3.15.4.1.1 Transrectal prostate biopsy

See section 3.16 for the results of a recent systematic review on which strategies are effective for reducing the risk of infective complications in men undergoing prostate biopsy.

3.15.4.1.2 Cystoscopy

The frequency of infectious complications after cystoscopy, standard urodynamic studies and diagnostic simple ureteroscopy in otherwise healthy individuals with sterile pre-operative urine is low [301-303]. In view of the very large number of cystoscopic examinations, the low infectious risk and the potential adverse effect on bacterial sensitivity, AMP is not recommended. However, bacteriuria, indwelling catheters, neurogenic LUTD and a history of urogenital infection are risk factors that must be considered [304-317].

3.15.4.2 Endourological treatment procedures (urinary tract entered)

3.15.4.2.1 Transurethral resection of the bladder (TURB)

There is little evidence for any benefit of AMP prior to TURB. Studies do not distinguish between simple fulguration (cystoscopy) and large or multiple tumours, or the presence or absence of necrotic material. Therefore, the present Guidelines recommend that clinicians choose the appropriate AMP regime based on tumour differentiation, see section 3.15.5 [303, 318-320].

3.15.4.2.2 Transurethral resection of the prostate (TURP)

Transurethral resection of the prostate is the best studied urological intervention. At least two meta-analyses of a large number of prospective, randomised controlled studies, including several thousand patients, showed a marked benefit of AMP with a relative risk reduction of 65% and 77% for bacteriuria and septicaemia, respectively [303, 318-320].

3.15.4.2.3 Ureteroscopy

Well-conducted prospective controlled trials on ureteroscopy are lacking. It is reasonable, however, to distinguish low-risk procedures, such as simple diagnostic and distal stone treatment in otherwise healthy individuals, from higher-risk procedures, such as treatment of proximal impacted stones with obstruction. Therefore the present Guidelines recommend clinicians choose the appropriate AMP regime based on the degree of severity, stone anatomic position and patient related risk factors, all of which are supported by a large database study [321].

3.15.4.2.4 Percutaneous nephrolithotripsy (PNL)

The risk of infection in PNL is high and use of AMP has been shown to significantly reduce the risk of infectious complications [99, 322-329]. A single dose was shown to be sufficient [330]. Retrograde intra-renal stone treatment could be expected to have a similar risk profile [321].

3.15.4.2.5 Shock-wave lithotripsy

No standard AMP is recommended. However, control of bacteriuria and AMP is recommended in cases of increased bacterial burden (e.g. indwelling catheter, nephrostomy tube, or infectious stones) [331-340].

3.15.4.3 Laparoscopic surgery

There has been a lack of sufficiently powered studies in laparoscopic urological surgery. However, it seems reasonable to manage laparoscopic surgical procedures in the same manner as the corresponding open procedures.

3.15.4.4 Nephrectomy, adrenalectomy

No standard AMP can be recommended, however, AMP may be considered optional in certain circumstances [341-345].

3.15.4.5 Prostatectomy

In open enucleation of prostatic adenoma, the risk of post-operative infection is particularly high and AMP is recommended [346]. As there are no studies on AMP in radical prostatectomy the use of AMP may be considered optional.

3.15.4.6 Cystectomy with bowel use

Single or one day dosage AMP is recommended, although prolonged operation and other morbidity risk factors might support the use of pre-emptive antimicrobial treatment, which should be < 72 hours. The choice of antimicrobials should focus on aerobic and anaerobic pathogens. Evidence is based on colorectal surgery, but experience is limited for specific urological interventions [347-350].

3.15.4.7 Post-operative drainage of the urinary tract

When continuous urinary drainage is left in place after surgery, prolongation of AMP is not recommended. Asymptomatic bacteriuria should not be treated.

3.15.4.8 Implantation of prosthetic devices: testis, penile prosthesis and artificial sphincter

Antimicrobial prophylaxis is recommended. When infectious complications occur in implant surgery, they are usually problematic and often result in removal of the prosthetic device. Diabetes mellitus is considered a specific risk factor for infection. Skin-related staphylococci are responsible for most infections, AMP used must be chosen to target these strains [351-354].

3.15.5 Recommendations for peri-operative antibacterial prophylaxis in urology

Recommendations				
Procedure	Comments	Antimicrobial prophylaxis	LE	GR
Diagnostic procedures				
Cystoscopy	Low frequency of infection. Consider individual risk factors for UTI (i.e. asymptomatic bacteriuria, history of febrile UTI)	No	1b	A
Urodynamic study	Low frequency of infections. Consider individual risk factors for UTI (i.e. asymptomatic bacteriuria, history of febrile UTI)	No	1a	A
Transrectal core biopsy of prostate	High risk of infection	Fluoroquinolones Trimethoprim ± sulphamethoxazole Targeted alternative	1b	A
Diagnostic ureteroscopy	No available studies	Optional	4	С
Common endourologic	al/endoscopic therapeutic procedu	ires (examples)		
Fulguration of small bladder tumours	Low frequency of infections.	Optional	2b	С
Transurethral resection of the bladder	Poor data. No concern given to burden of tumour, i.e. size, multiplicity, necrosis	Trimethoprim ± sulphamethoxazole Aminopenicillin/ Beta-lactamase	2b	С
Transurethral resection of the prostate	High risk of infection	inhibitor Cephalosporin group 2 or 3	1a	A
Shock-wave lithotripsy	Low frequency of infections	-	1a	A
Ureteroscopy for stone management	Distal stone removal.		2b	В
Percutaneous and retrograde intra-renal stone management	High risk of infection		1b	A
Common open and/or	Common open and/or laparoscopic surgery			
Nephrectomy ± ureterectomy Adrenalectomy Radical prostatectomy	Surgical site infection/wound infection poorly documented Secondary post-operative catheter- related asymptomatic bacteriuria/ UTI	Optional	3	C
Planned scrotal surgery, vasectomy, surgery for varicocele	Conflicting data	No	3	С

Prosthetic implants, artificial sphincter	Limited documentation	Aminopenicillin/ Beta-lactamase inhibitor Piperacillin/Tazobactam	3	В
Uretero-pelvic junction repair		Optional	4	С
Partial bladder resection		Optional	3	С
Cystectomy with urine deviation	High risk of infection	Cefuroxim Aminopenicillin/ Beta-lactamase inhibitor + Metronidazole	2a	В

3.16 Prostate biopsy

3.16.1 Evidence question

Which strategies are effective for reducing the risk of infective complications in men undergoing prostate biopsy?

3.16.2 Epidemiology, Aetiology and Pathophysiology

Histological examination of needle biopsies of the prostate is the principle method for prostate cancer diagnosis. Prostate biopsy is a common procedure in high-resource countries with, for example, about 32,000 procedures performed in England during 2013 [355] giving a rate of 2.6/1,000 men at risk per year. Transrectal ultrasound-guided biopsy (TRUS) is the current standard technique although the transperineal route is also used [356]. Infection is the most clinically significant harm experienced by men following prostate biopsy. There is some evidence that the risk is increasing [357]. Infection generally occurs by implantation of rectal commensal organisms into the prostate, urethra or bloodstream during needle insertion. Severity of infection will depend on bacterial inoculum, virulence and status of host defence.

3.16.3 Diagnostic Evaluation

Urine culture prior to prostate biopsy has an uncertain predictive value [358].

3.16.4 Disease Management

The focus is on prevention of infectious complications. Possible strategies include antimicrobial prophylaxis and non-antimicrobial strategies, the effectiveness of which will be described in this section. Established infection is treated according to standard pathways [355].

3.16.5 Evidence summary

A systematic search of the literature to March 2015 identified 1,556 titles of which 189 were selected for full text review and 93 RCTs were included [359-453]

3.16.6 Non-antimicrobial interventions

3.16.6.1 Number of biopsy cores

Meta-analysis of seven trials involving 1,290 men found no evidence that extended biopsy (> 6-24 cores) templates resulted in more infectious complications than standard templates (6-12 cores) [(95% Cls) = 1.71 (0.70 - 4.16)] [359-365].

3.16.6.2 Peri-prostatic injection of local anaesthetic

A meta-analysis of 25 RCTs with 3,533 participants found no evidence that use of peri-prostatic injection of local anaesthesia resulted in a higher rate of infectious complications compared to no injection [366-370, 372-388, 429, 430, 434]. Four other RCTs with 497 patients compared different numbers of injections performed for peri-prostatic injection of local anaesthetic. Here, no difference was found in infective complications [RR (95% Cls) = 1.51 (0.26 - 8.97)] [405-408]

3.16.6.3 Route of biopsy

Three RCTs involving 646 men compared transrectal and transperineal routes of biopsy. Overall two men (0.4%) suffered infectious complications after transperineal biopsy, compared to five (1.1%) after transrectal biopsy [RR (95% CIs) = 0.45 (0.10 - 1.97)]. The studies were heterogeneous in design, did not state how infectious outcomes were assessed and used differing antimicrobial prophylaxis between arms.

3.16.6.4 Rectal preparation

A meta-analysis of three studies including 209 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications [RR (95% Cis) =0.76

(0.40 to 1.46)] [400, 447, 450].

Meta-analysis of six trials including 1,373 men showed that use of a rectal povidone-iodine preparation before biopsy in addition to antimicrobial prophylaxis resulted in a lower rate of infectious complications [RR (95% Cls) = 0.58 (0.43 to 0.76)] [392-397]. Single RCTs showed no evidence of benefit for perineal skin disinfection [398] but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [453].

3.16.6.5 Other interventions

Combining data from two RCTs with 253 participants showed that biopsy using disposable needle guides resulted in nine infectious complications compared to 22 with reusable biopsy needle guides. The difference was not significant [RR (95% CIs) = 0.51 (0.24 to 1.06)] [402, 403]. A single RCT found no evidence that disinfection of a single patient use needle between cores resulted in fewer infectious complications [404]. Another single study evaluated the needle size and did not find significant differences between a 16 G and an 18 G needle size [446].

Recommendation	LE	GR
Use rectal cleansing with povidone-iodine in men prior to transrectal prostate biopsy.	1a	B*
*Downgraded as highest quality trial in meta-analysis showed no difference [391].		

3.16.7 Antimicrobial prophylaxis

The meta-analysis on eleven studies with 1,753 patients showed significantly reduced infections after biopsy when using AMP as compared to placebo/control [RR (95% Cls) = 0.56 (0.40 to 0.77)] [393, 397, 413, 423, 431, 433, 437, 442, 447, 448, 452]. Thus, antimicrobial prophylaxis is strongly recommended. However, the choice of regimens and duration of prophylaxis remains debatable. Most commonly fluorochinolones are applied [419, 421, 422, 431, 435, 451]. Due to the increase in fluorochinolone resistance recent studies have investigated alternatives like fosfomycin trometamol [435], or suggest targeted antimicrobial prophylaxis based on rectal swab [401]. While the available Cochrane review of 2011 suggests a one-day prophylaxis with a single agent [454], a recent systematic analysis has pointed towards an augmented antimicrobial therapy [455]. A meta-analysis on this issue by the guideline panel is ongoing on and will be finalised next year.

Recommendation	LE	GR
Use antimicrobial prophylaxis in men prior to transrectal prostate biopsy.	1a	А

5. CONFLICT OF INTEREST

All members of the EAU Urological Infections Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website: <u>http://www.uroweb.org/guidelines/</u>. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Urolithiasis Guidelines Panel has prepared these guidelines to help urologists assess evidence-based management of stones/calculi in the urinary tract and incorporate recommendations into clinical practice. Management of bladder stones is not addressed in these guidelines. This document covers most aspects of the disease, which is still a cause of significant morbidity despite technological and scientific advances. The Panel is aware of the geographical variations in healthcare provision.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account.

Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urolithiasis Guidelines Panel consists of an international group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: <u>http://uroweb.org/guideline/urolithiasis/</u>.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Also a number of scientific publications are available [1-3]. All documents can be accessed through the EAU website: <u>http://uroweb.org/guideline/urolithiasis/</u>.

1.4 Publication history and summary of changes

1.4.1 **Publication history**

The EAU Urolithiasis Guidelines were first published in 2000. This 2017 document presents a limited update of the 2016 publication of the EAU Urolithiasis Guidelines.

1.4.2 Summary of changes

The literature for the entire document has been assessed and updated, whenever relevant (see Methods section below).

Key changes for the 2017 publication:

3.4.1.1 Renal colic

Summary of evidence	LE
Administration of daily α -blockers seems to reduce colic episodes, although controversy	1b
remains in the published literature.	

3.4.2.1.3.2 Best clinical practice

Summary of evidence - Number of shock waves, energy setting and repeat treatment	
sessions	
Stepwise power ramping prevents renal injury.	1b
Clinical experience has shown that repeat sessions are feasible (within one day for ureteral	4
stones).	
Optimal shock wave frequency is 1.0 to 1.5Hz.	1a

3.4.2.2 Indication for active stone removal of renal stones

Recommendation	GR
Offer active treatment for renal stones in case of stone growth, de novo obstruction,	С
associated infection, and acute and/or chronic pain.	

3.4.3.1.2 Pharmacological treatment, Medical expulsive therapy (MET)

Summary of evidence	LE
Medical expulsion therapy (MET) seems to be efficacious treating patients with ureteric stones	1a
who are amenable to conservative management. The greatest benefit might be among those	
with larger (distal) stones.	

Recommendations	LE	GR
Select patients for an attempt at spontaneous passage or MET, based on well-	4	С
controlled pain, no clinical evidence of sepsis, and adequate renal functional reserve.		
Offer α -blockers as MET as one of the treatment options, in particular for (distal)		А
ureteral stones > 5 mm.		
Counsel patients regarding the controversies in the literature, attendant risks of MET,	1b	A*
including associated drug side effects. Inform the patient that α -blockers as MET are		
administered off-label ^{†**} .		

† It is not known if tamsulosin harms the human foetus or if it is found in breast milk.

*Upgraded based on panel consensus.

**MET in children cannot be recommended due to the limited data in this specific population.

3.4.3.1.4.1.2 Best clinical practice in ureterenoscopy

Summary of evidence	LE
In ureterorenoscopy (URS) (in particular for renal stones), pre-stenting has been shown to	1b
improve outcome.	

3.4.3.3 Selection of procedure for active removal of ureteral stones

Recommendation	GR
In obese patients ureterorenoscopy is a safe and efficient option to remove renal stones.	2b
Ureterorenoscopy in morbidly obese patients have significantly higher complication rates as	1a
compared to normal weight patients.	

2. METHODS

2.1 Data identification

For the 2017 Urolithiasis Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature.

A broad and comprehensive scoping exercise covering all areas of the guideline was performed. The search was limited to studies representing high levels of evidence only (i.e. systematic reviews with metaanalysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies only) published in the English language. The search was restricted to articles published between September 1st 2015 and October 12th, 2016. Databases covered by the search included Medline, EMBASE and the Cochrane Libraries. A total of 751 unique records were identified, and screened for relevance. The search strategy is published online: <u>http://uroweb.org/guideline/urolithiasis/?type=appendices-publications</u>.

In addition to the new literature identified through the electronic searches, the authors included one additional, more recent, article as of significant relevance for two sections (3.4.1.1 Renal colic & 3.4.3.1.2 Pharmacological treatment, Medical expulsive therapy (MET) [4].

Two sections of the text have been updated based on two systematic reviews (SRs). These SRs were performed using standard Cochrane SR methodology; <u>http://www.cochranelibrary.com/about/about-cochranesystematic-reviews.html</u>.

Systematic review topics:

- Tract sizes in miniaturized percutaneous nephrolithotomy: A systematic review [5].
- What are the benefits and harms of ureterenoscopy (URS) compared with shock-wave lithotripsy (SWL) in the treatment of upper ureteral stones (UUS): A systematic review [6].

•

Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <u>http://uroweb.org/guidelines/</u>.

A list of Associations endorsing the EAU Guidelines can also be viewed on line at the above address.

2.2 Review

The 2015 Urolithiasis Guidelines were subjected to peer review prior to publication.

2.3 Future goals

Further results on ongoing and new SRs will be included in the 2018 update of the Urolithiasis Guidelines.

3. GUIDELINES

3.1 Prevalence, aetiology, risk of recurrence

3.1.1 Introduction

Stone incidence depends on geographical, climatic, ethnic, dietary and genetic factors. The recurrence risk is basically determined by the disease or disorder causing the stone formation. Accordingly, the prevalence rates for urinary stones vary from 1% to 20% [8]. In countries with a high standard of life such as Sweden, Canada or the US, renal stone prevalence is notably high (> 10%). For some areas an increase of more than 37% over the last 20 years has been reported [9-11].

Stones can be classified into those caused by: infection, or non-infectious causes (infection- and non-infection stones); genetic defects [12]; or adverse drug effects (drug stones) (Table 3.1.1).

Table 3.1.1: Stones classified by aetiology*

Non-infection stones
Calcium oxalate
Calcium phosphate
Uric acid
Infection stones
Magnesium ammonium phosphate
Carbonate apatite
Ammonium urate
Genetic causes
Cystine
Xanthine
2,8-Dihydroxyadenine
Drug stones

*See Section 4.4.2

3.1.2 Stone composition

Stone composition is the basis for further diagnostic and management decisions. Stones are often formed from a mixture of substances. Table 3.1.2 lists the clinically most relevant substances and their mineral components.

Table 3.1.2: Stone composition

Chemical name	Mineral name	Chemical formula
Calcium oxalate monohydrate	Whewellite	CaC ₂ O ₄ .H ₂ O
Calcium oxalate dihydrate	Wheddelite	CaC ₂ O ₄ .2H ₂ O
Basic calcium phosphate	Apatite	Ca ₁₀ (PO ₄) ₆ .(OH) ₂
Calcium hydroxyl phosphate	Carbonite apatite	Ca ₅ (PO ₃) ₃ (OH)
b-tricalcium phosphate	Whitlockite	Ca ₃ (PO ₄) ₂
Carbonate apatite phosphate	Dahllite	Ca ₅ (PO ₄) ₃ OH
Calcium hydrogen phosphate	Brushite	PO ₄ .2H ₂ O
Calcium carbonate	Aragonite	CaCO ₃
Octacalcium phosphate		Ca ₈ H ₂ (PO ₄) ₆ .5H ₂ O
Uric acid	Uricite	$C_5H_4N_4O_3$
Uric acid dihydrate	Uricite	C ₅ H ₄ O ₃ -2H ₂ 0
Ammonium urate		$NH_4C_5H_3N_4O_3$
Sodium acid urate monohydrate		NaC ₅ H ₃ N ₄ O ₃ .H ₂ O
Magnesium ammonium phosphate	Struvite	MgNH ₄ PO ₄ .6H ₂ O
Magnesium acid phosphate trihydrate	Newberyite	MgHPO ₄ .3H ₂ O
Magnesium ammonium phosphate monohydrate	Dittmarite	MgNH ₄ (PO ₄).1H ₂ O

3.1.3 Risk groups for stone formation

The risk status of stone formers is of particular interest because it defines the probability of recurrence or regrowth, and is imperative for pharmacological treatment.

About 50% of recurrent stone formers have just one lifetime recurrence [10, 13]. Highly recurrent disease is observed in slightly more than 10% of patients. Stone type and disease severity determine low- or high risk of recurrence (Table 3.1.3) [14, 15].

Table 3.1.3: High-risk stone formers [14-25]

General factors
Early onset of urolithiasis (especially children and teenagers)
Familial stone formation
Brushite-containing stones (CaHPO ₄ .2H ₂ O)
Uric acid and urate-containing stones
Infection stones
Solitary kidney (the kidney itself does not particularly increase the risk of stone formation, but prevention of
stone recurrence is of more importance)
Diseases associated with stone formation
Hyperparathyroidism
Metabolic syndrome
Nephrocalcinosis
Polycystic kidney disease (PKD)
Gastrointestinal diseases (i.e., jejuno-ileal bypass, intestinal resection, Crohn's disease, malabsorptive
conditions, enteric hyperoxaluria after urinary diversion) and bariatric surgery [20]
Sarcoidosis
Spinal cord injury, neurogenic bladder
Genetically determined stone formation
Cystinuria (type A, B and AB)
Primary hyperoxaluria (PH)
Renal tubular acidosis (RTA) type I
2,8-Dihydroxyadeninuria
Xanthinuria
Lesch-Nyhan syndrome
Cystic fibrosis
Drug-induced stone formation (see Table 4.11)
Anatomical abnormalities associated with stone formation
Medullary sponge kidney (tubular ectasia)
Ureteropelvic junction (UPJ) obstruction
Calyceal diverticulum, calyceal cyst
Ureteral stricture
Vesico-uretero-renal reflux
Horseshoe kidney
Ureterocele
Environmental factors
Chronic lead exposure

3.2 Classification of stones

Urinary stones can be classified according to size, location, X-ray characteristics, aetiology of formation, composition, and risk of recurrence [10, 26-28].

3.2.1 Stone size

Stone size is usually given in one or two dimensions, and stratified into those measuring up to 5, 5-10, 10-20, and > 20 mm in largest diameter.

3.2.2 Stone location

Stones can be classified according to anatomical position: upper, middle or lower calyx; renal pelvis; upper, middle or distal ureter; and urinary bladder. Treatment of bladder stones is not discussed in these guidelines.

3.2.3 X-ray characteristics

Stones can be classified according to plain X-ray appearance [kidney-ureter-bladder (KUB) radiography] (Table 3.2.1), which varies according to mineral composition [28]. Non-contrast-enhanced computed tomography (NCCT) can be used to classify stones according to density, inner structure and composition, which can affect treatment decisions (Section 3.4.1.4.4) [27, 28].

Table 3.2.1: X-ray characteristics

Radiopaque	Poor radiopacity	Radiolucent
Calcium oxalate dihydrate	Magnesium ammonium phosphate	Uric acid
Calcium oxalate monohydrate	Apatite	Ammonium urate
Calcium phosphates	Cystine	Xanthine
		2,8-Dihydroxyadenine
		Drug-stones (Section 4.11)

Stratification of stones according to aetiology, composition and risk of recurrence is addressed in Section 3.1.

3.3 Diagnostic evaluation

3.3.1 Diagnostic imaging

The clinical situation will inform on the most appropriate imaging modality, which will differ for a suspected ureteral stone or a suspected renal stone.

Standard evaluation includes a detailed medical history and physical examination. Patients with ureteral stones usually present with loin pain, vomiting, and sometimes fever, but may also be asymptomatic [29].

Ultrasound (US) should be used as the primary diagnostic imaging tool, although pain relief, or any other emergency measures should not be delayed by imaging assessments. Ultrasound is safe (no risk of radiation), reproducible and inexpensive. It can identify stones located in the calices, pelvis, and pyeloureteric and vesicoureteric junctions (US with filled bladder), as well as in patients with upper urinary tract dilatation. Ultrasound has a sensitivity of 45% and specificity of 94% for ureteric stones and a sensitivity of 45% and specificity of 94% for ureteric stones and a sensitivity of 45% and specificity of 94% for ureteric stones and a sensitivity of 45% and specificity of 88% for renal stones [30, 31].

The sensitivity and specificity of KUB (kidney-ureter-bladder radiography) is 44-77% and 80-87%, respectively [32]. Kidney-ureter-bladder radiography should not be performed if NCCT is considered [33]. However, KUB is helpful in differentiating between radiolucent and radiopaque stones and be used for comparison during follow-up.

With fever or solitary kidney, and when diagnosis is doubtful, immediate imaging is indicated. 4	Recommendation	LE	GR
	With fever or solitary kidney, and when diagnosis is doubtful, immediate imaging is indicated.	4	A*

*Upgraded following panel consensus.

3.3.1.1 Evaluation of patients with acute flank pain/suspected ureteral stones

Non-contrast-enhanced computed tomography has become the standard for diagnosing acute flank pain, and has replaced intravenous urography (IVU). Non-contrast-enhanced computed tomography can determine stone diameter and density. When stones are absent, the cause of abdominal pain should be identified. In evaluating patients with suspected acute urolithiasis, NCCT is significantly more accurate than IVU [34].

Recommendation	LE	GR
Following initial ultrasound assessment, use non-contrast-enhanced computed tomography	1a	А
to confirm stone diagnosis in patients with acute flank pain, as it is superior to intravenous		
urography.		

Non-contrast-enhanced computed tomography can detect uric acid and xanthine stones, which are radiolucent on plain films, but not indinavir stones [35]. Non-contrast-enhanced computed tomography can determine stone density, inner structure of the stone and skin-to-stone distance and surrounding anatomy; all of which affect selection of treatment modality [28, 36-38]. The advantage of non-contrast imaging must be balanced against loss of information on renal function and urinary collecting system anatomy, as well as higher radiation dose [39-42].

Radiation risk can be reduced by low-dose CT, which may, however, be difficult to introduce in standard clinical practice [43, 44]. In patients with a body mass index (BMI) < 30, low-dose CT has been shown to have a sensitivity of 86% for detecting ureteric stones < 3 mm and 100% for calculi > 3 mm [45]. A metaanalysis of prospective studies [46] has shown that low-dose CT diagnosed urolithiasis with a pooled sensitivity of 96.6% (95% CI: 95.0-97.8) and specificity of 94.9% (95% CI: 92.0-97.0).

Dual-energy CT can differentiate uric acid containing stones from calcium-containing stones [47].

3.3.1.2 Radiological evaluation of patients with renal stones

Intravenous urography can provide information about renal function, the anatomy of the collecting system as well as the level of an obstruction. Non-contrast-enhanced CT allows for rapid 3D data acquisition including information on stone size and density, skin-to-stone distance and surrounding anatomy, but at the cost of increased radiation exposure. Low-dose and ultra-low-dose protocols seem to yield comparable results as standard-dose protocols with the exception of detection of very small stones or stones in obese patients [45, 46].

A small randomised study showed that in supine PNL, pre-operative planning using CT compared to IVU, resulted in easier access and shorter operating times [48].

In case stone removal is planned, the renal collecting system needs to be assessed.

Recommendations	LE	GR
Perform a contrast study if stone removal is planned and the anatomy of the renal collecting	3	A*
system needs to be assessed.		
Use enhanced computed tomography in complex cases because it enables 3D reconstruction	2a	С
of the collecting system, as well as measurement of stone density and skin-to-stone distance.		
Intravenous urography may also be used.		

*Upgraded based on panel consensus.

3.3.2 Diagnostics - metabolism-related

Each emergency patient with urolithiasis needs a succinct biochemical work-up of urine and blood besides imaging. At that point, no distinction is made between high- and low-risk patients for stone formation.

Table 3.3.1: Recommendations: basic laboratory analysis - emergency urolithiasis patients

[15, 16, 49, 50]

Recommendations	GR
Urine	
Dipstick test of spot urine sample	A*
red cells	А

Perform a coagulation test (partial thromboplastin time [PTT] and international normalised ratio [INR]) if	A*
intervention is likely or planned.	

*Upgraded based on panel consensus.

3.3.2.1 Basic laboratory analysis - non-emergency urolithiasis patients

Biochemical work-up is similar for all stone patients. However, if no intervention is planned, examination of sodium, potassium, C-reactive protein, and blood coagulation time can be omitted.

Only patients at high risk for stone recurrence should undergo a more specific analytical programme [15]. Stone-specific metabolic evaluation is described in Chapter 4.

The easiest method for diagnosing stones is by analysis of a passed stone using a validated method as listed below (see 3.2.2). Once the mineral composition is known, a potential metabolic disorder can be identified.

3.3.2.2 Analysis of stone composition

Stone analysis should be performed in all first-time stone formers.

In clinical practice, repeat stone analysis is needed in the case of:

- recurrence under pharmacological prevention;
- early recurrence after interventional therapy with complete stone clearance;
- late recurrence after a prolonged stone-free period [49, 51].

Patients should be instructed to filter their urine to retrieve a concrement for analysis. Stone passage and restoration of normal renal function should be confirmed.

The preferred analytical procedures are infrared spectroscopy (IRS) or X-ray diffraction (XRD) [52-54]. Equivalent results can be obtained by polarisation microscopy. Chemical analysis (wet chemistry) is generally deemed to be obsolete [52].

Recommendations	LE	GR
Perform stone analysis in first-time formers using a valid procedure (X-ray diffraction or infrared	2	А
spectroscopy).		
Repeat stone analysis in patients:	2	В
 presenting with recurrent stones despite drug therapy; 		
• with early recurrence after complete stone clearance;		
with late recurrence after a long stone-free period because stone composition may		
change.		

3.3.3 Diagnosis in special groups and conditions

3.3.3.1 Diagnostic imaging during pregnancy

In pregnant women diagnostic imaging (exposure to ionising radiation) might be associated with teratogenic risks and development of (childhood) malignancies. The risk for the child crucially depends on gestational age and radiation dose delivered. X-ray imaging during the first trimester should be reserved for patients in which alternative imaging methods have failed [55, 56].

Ultrasound (when necessary using change in renal resistive index and transvaginal/transabdominal US with a full bladder) has become the primary radiological diagnostic tool when evaluating pregnant patients suspected of renal colic. However, normal physiological changes in pregnancy can mimic ureteral obstruction [57].

Magnetic resonance imaging (MRI) can be used, as a second-line procedure, to define the level of urinary tract obstruction, and to visualise stones as a filling defect [58, 59].

Low dose CT protocols reduce the radiation exposure and are currently recommended to be used judicially in pregnant women as a last-line option [60, 61].

LE	GR
1a	A*
3	С
3	С
	LE 1a 3 3

*Upgraded following panel consensus.

3.3.3.2 Children

Children with urinary stones have a high risk of recurrence; therefore, standard diagnostic procedures for highrisk patients apply (Section 3.1.3 and Chapter 4). The most common non-metabolic disorders facilitating stone formation are vesicoureteral reflux (VUR), UPJ obstruction, neurogenic bladder, and other voiding difficulties [62].

Summary of evidence	LE
In children, the most common non-metabolic disorders facilitating stone formation are vesicoureteral	4
reflux, ureteropelvic junction obstruction, neurogenic bladder, and other voiding difficulties [62].	

3.3.3.2.1 Diagnostic imaging

When selecting diagnostic procedures to identify urolithiasis in children, it should be remembered that these patients might be uncooperative, require anaesthesia, and may be sensitive to ionising radiation [63-65]. Again, the principle of ALARA (As Low As Reasonably Achievable) should be observed.

3.3.3.2.2 Ultrasound

Ultrasound is the primary imaging technique [63] in children. Its advantages are absence of radiation and no need for anaesthesia. Imaging should include both the fluid-filled bladder with adjoining portion of the ureters, as well as the upper ureter [66-70].

Colour Doppler US shows differences in the ureteric jet [67] and resistive index of the arciform arteries of both kidneys, which are indicative of the grade of obstruction [68].

Nevertheless, US fails to identify stones in > 40% of children [69-72] (LE: 4), and provides limited information on renal function.

3.3.3.2.3 Plain films (KUB radiography)

KUB radiography can help to identify stones and their radiopacity, and facilitate follow-up.

3.3.3.2.4 Intravenous urography (IVU)

The radiation dose for IVU is comparable to that for voiding cystourethrography (0.33 mSV) [73]. However, the need for contrast medium injection is a major drawback.

3.3.3.2.5 Helical computed tomography (CT)

Recent low-dose CT protocols have been shown to significantly reduce radiation exposure [42, 74].

In children, only 5% of stones escape detection by NCCT [60, 67, 74]. Sedation or anaesthesia is rarely needed with modern high-speed CT equipment.

3.3.3.2.6 Magnetic resonance urography (MRU)

Magnetic resonance urography cannot be used to detect urinary stones. However, it might provide detailed anatomical information about the urinary collecting system, the location of an obstruction or stenosis in the ureter, and renal parenchymal morphology [75].

Recommendations	GR
In all children, complete a metabolic evaluation based on stone analysis.	А
Collect stone material for analysis to classify the stone type.	A*
In children, use ultrasound as first-line imaging modality when a stone is suspected; it should include	В
the kidney, fluid-filled bladder and the ureter next to the kidney and the (filled) bladder.	
If ultrasound will not provide the required information, perform a kidney-ureter-bladder radiography (or	В
low-dose non-contrast-enhanced computed tomography).	

*Upgraded following panel consensus.

3.4 Disease management

3.4.1 Management of patients with renal or ureteral stones

Treatment decisions for upper urinary tract calculi are based on several general aspects such as stone composition, stone size, and symptoms.

3.4.1.1 Renal colic

Pain relief

Pain relief is the first therapeutic step in patients with an acute stone episode [76].

Non-steroidal anti-inflammatory drugs (NSAIDs) including metamizole (dipyrone), a pyrazolone NSAID, are effective in patients with acute stone colic [77, 78], and have better analgesic efficacy than opioids. The addition of antispasmodics to NSAIDS does not result in better pain control and data on other types of non-opioid, non-NSAID medication is scarce [79]. Patients receiving NSAIDs are less likely to require further analgesia in the short term. It should be taken into consideration that the use of diclofenac and ibuprofen increased major coronary events. Diclofenac is contraindicated in patients with congestive heart failure (New York Heart Association class II-IV), ischaemic heart disease and peripheral arterial- and cerebrovascular disease. Patients with significant risk factors for cardiovascular events should be treated with diclofenac only after careful consideration. As risks increase with dose and duration, the lowest effective dose should be used for the shortest duration [80, 81].

Opioids, particularly pethidine, are associated with a high rate of vomiting compared to NSAIDs, and carry a greater likelihood of further analgesia being needed [82] (see below). If an opioid is used, it is recommended that it is not pethidine.

Prevention of recurrent renal colic

Facilitation of passage of ureteral stones is discussed in Section 3.4.3.1.2.

For patients with ureteral stones that are expected to pass spontaneously, NSAID tablets or suppositories (e.g., diclofenac sodium, 100-150 mg/day, 3-10 days) may help reduce inflammation and the risk of recurrent pain [83, 84]. Although diclofenac can affect renal function in patients with already reduced function, it has no functional effect in patients with normal renal function [85] (LE: 1a).

In a double-blind, placebo-controlled trial, recurrent pain episodes of stone colic were significantly fewer in patients treated with NSAIDs (as compared to no NSAIDs) during the first seven days of treatment [86]. Contrary to earlier findings, daily α -blockers did not reduce recurrent pain or analgesia requirements in patients with distal ureteral stones in two recent large high-quality studies [87, 88] (Section 3.4.3.1.2). The most recent SR and meta-analysis by Hollingsworth *et al.* [4] addressed pain reduction as a secondary outcome and concluded that MET seems efficacious in reducing pain episodes of patients with ureteric stones who are amenable to conservative management. Patients benefitting most might be those with larger (distal) stones.

If analgesia cannot be achieved medically, drainage, using stenting or percutaneous nephrostomy or stone removal, should be performed.

Recommendations	GR
Provide immediate pain relief in acute stone episodes.	А
Whenever possible, offer a non-steroidal anti-inflammatory as the first drug of choice. e.g. metamizol	А
(dipyrone); alternatively, depending on cardio-vascular risk factors, diclofenac*, indomethacin or	
ibuprofen**.	
Offer hydromorphine, pentazocine or tramadol as a second choice.	С
*Affects glomerular filtration rate (GFR) in patients with reduced renal function (LE: 2a).	

**Recommended to counteract recurrent pain after ureteral colic.

Summary of evidence	LE
Administration of daily α -blockers seems to reduce colic episodes, although controversy remains in	1b
the published literature.	
For symptomatic ureteral stones, urgent stone removal as first-line treatment is a feasible option in	1b
selected cases (see text).	

3.4.1.2 Management of sepsis and/or anuria in obstructed kidney

The obstructed kidney with all signs of urinary tract infection (UTI) and/or anuria is a urological emergency. Urgent decompression is often necessary to prevent further complications in infected hydronephrosis secondary to stone-induced, unilateral or bilateral renal obstruction.

Decompression

Currently, there are two options for urgent decompression of obstructed collecting systems:

- placement of an indwelling ureteral stent;
- percutaneous placement of a nephrostomy tube.

There is little evidence to support the superiority of percutaneous nephrostomy over retrograde stenting for primary treatment of infected hydronephrosis. There is no good quality evidence to suggest that ureteric stenting has more complications than percutaneous nephrostomy [89, 90].

Only one RCT [91] compared different modalities of decompression of acute infected hydronephrosis. The complications of percutaneous nephrostomy insertion have been reported consistently, but those of ureteric stent insertion are less well described [89]. Definitive stone removal should be delayed until the infection is cleared following a complete course of antimicrobial therapy. A small RCT showed the feasibility of immediate ureteroscopic stone removal combined with appropriate antibiotic regimen; however, at the cost of longer hospital stay and higher analgesic requirements [92].

In children, ureteric stents might have some advantage compared to PCN in case of acute anuria [93].

Summary of evidence	LE
For decompression of the renal collecting system, ureteral stents and percutaneous nephrostomy	1b
catheters are equally effective.	

Recommendations	LE	GR
Urgently decompress the collecting system in case of sepsis with obstructing stones, using	1b	А
percutaneous drainage or ureteral stenting.		
Delay definitive treatment of the stone until sepsis is resolved.	1b	А

Further measures

Following urgent decompression of the obstructed and infected urinary collecting system, both urine- and blood samples should be sent for culture-antibiogram sensitivity testing, and antibiotics should be initiated immediately thereafter or continued if initiated prior to testing. The regimen should be re-evaluated in the light of the culture-antibiogram test. Although clinically well accepted, the impact of a second antibiogram test on treatment outcome has not yet been evaluated. Intensive care might become necessary [94].

Recommendations	GR		
Collect (again) urine for antibiogram test following decompression.	A*		
Start antibiotics immediately (+ intensive care if necessary).			
Re-evaluate antibiotic regimen following antibiogram findings.			

*Upgraded based on panel consensus.

3.4.1.3 General recommendations and precautions for stone removal

3.4.1.3.1 Antibiotic therapy

Urinary tract infections should always be treated if stone removal is planned. In patients with clinically significant infection and obstruction, drainage should be performed for several days, via a stent or percutaneous nephrostomy, before starting stone removal.

Recommendation	GR
Obtain a urine culture or perform urinary microscopy before any treatment is planned.	A*
*Upgraded following panel consensus.	

Perioperative antibiotic prophylaxis

For prevention of infection following ureterenoscopy and percutaneous stone removal, no clear-cut evidence exists [95, 96]. In a review of a large database of patients undergoing percutaneous nephrolithotomy, it was found that in patients with negative baseline urine culture, antibiotic prophylaxis significantly reduced the rate of post-operative fever and other complications [97]. Single dose administration was found to be sufficient [98].

Recommendations	LE	GR
Exclude or treat urinary tract infections prior to stone removal.	1b	А
Offer perioperative antibiotic prophylaxis to all patients undergoing endourological treatment.	1b	A*

3.4.1.3.2 Antithrombotic therapy and stone treatment

Patients with a bleeding diathesis, or receiving antithrombotic therapy, should be referred to an internist for appropriate therapeutic measures before deciding on stone management [99-103]. In patients with an uncorrected bleeding diathesis, the following are at elevated risk of haemorrhage or perinephric haematoma (PNH) (high-risk procedures):

- shock wave lithotripsy (SWL) (hazard ratio of PNH up to 4.2 during anticoagulant/antiplatelet medication [104] [LE: 2]);
- percutaneous nephrolithotripsy;
- percutaneous nephrostomy;
- laparoscopic surgery;
- open surgery [99, 105, 106].

Shock wave lithotripsy is feasible and safe after correction of the underlying coagulopathy [107-111]. In the case of an uncorrected bleeding disorder or continued antithrombotic therapy, ureterorenoscopy (URS), in contrast to SWL and PNL, might offer an alternative approach since it is associated with less morbidity [112-116]. Only data on flexible ureterorenoscopy are available which support the superiority of URS in the treatment of proximal ureteric stones [113, 117].

Table 3.4.1: Risk stratification for bleeding [101-103, 118]

Low-risk bleeding procedures	Cystoscopy		
	Flexible cystoscopy		
	Ureteral catheterisation		
	Extraction of ureteric stentUreterenoscopy		
High-risk bleeding procedures	Shock wave lithotripsy		
	Percutaneous nephrostomy		
	Percutaneous nephrolithotripsy		

Table 3.4.2: Suggested strategy for antithrombotic therapy in stone removal [101-103]

(In collaboration with cardiologist/internist weigh the risks and benefits of discontinuation of therapy, vs. delaying elective surgical procedures.)

	Bleeding risk of	Risk of thromboembolism		sm
	planned procedure	Low risk	Intermediate risk	High risk
Warfarin	Low-risk procedure	May be continued	Bridging therapy	Bridging therapy
Dabigatran Rivaroxaban Apixaban	High-risk procedure	May be temporarily discontinued at appropriate interval. Bridging therapy is strongly recommended.	Bridging therapy	Bridging therapy
Aspirin	Low-risk procedure	Continue	Continue	Elective surgery: postpone. Non deferrable surgery: continue
	High-risk procedure	Discontinue	Elective surgery: postpone. Non-deferrable surgery: continue, if is possible.	Elective surgery: postpone. Non-deferrable surgery: continue.
Thienopyridine agents (P2Y12 receptor inhibitors)	Low-risk procedure	Discontinue five days before intervention. Resume within 24-72 hours with a loading dose.	Continue	Elective surgery: postpone. Non-deferrable surgery: continue.
	High-risk procedure	Discontinue five days before intervention and resume within 24-72 hours with a loading dose.	Elective surgery: postpone. Non-deferrable surgery: discontinue five days before procedure and resume within 24-72 hours with a loading dose. Bridging therapy - GPIIb/IIIa inhibitors if aspirin is discontinued	Elective surgery: postpone. Non-deferrable surgery: discontinue five days before procedure and resume within 24-72 hours, with a loading dose. Bridging therapy - GPIIb/IIIa inhibitors.
Recommendations	LE	GR		
--	----	----		
Offer active surveillance to patients at high risk for thrombotic complications in the presence of	4	С		
an asymptomatic calyceal stone.				
Decide on temporary discontinuation, or bridging of antithrombotic therapy in high-risk	3	В		
patients, in consultation with the internist.				
Prefer retrograde (flexible) URS if stone removal is essential and antithrombotic therapy cannot	2a	A*		
be discontinued, since it is associated with less morbidity.				

*Upgraded based on panel consensus.

3.4.1.3.3 Obesity

Obesity can cause a higher risk due to anesthesiological requirements, and a lower success rate after SWL and PNL.

3.4.1.3.4 Stone composition

Stones composed of brushite, calcium oxalate monohydrate, or cystine are particularly hard as well as stones with high density on NCCT [36]. Percutaneous nephrolithotomy or ureterorenoscopy (RIRS) and URS are alternatives for removal of large SWL-resistant stones.

Recommendations	LE	GR
Consider the stone composition before deciding on the method of removal, based on patient	2-4	B*
history, former stone analysis of the patient or Hounsfield unit (HU) on unenhanced computed		
tomography (CT). Stones with density > 1,000 HU on non-contrast-enhanced CT are less likely		
to be disintegrated by shock wave lithotripsy.		
Attempt to dissolve radiolucent stones (See Section 3.4.2.1.2.2).	2a	В

*Upgraded in parts based on panel consensus.

3.4.1.3.5 Steinstrasse

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter, may interfere with the passage of urine [119]. Steinstrasse occurs in 4-7% cases of SWL [120], and the major factor in the development of steinstrasse formation is stone size [121].

A major problem of steinstrasse is ureteral obstruction, which may be silent in up to 23% of cases. A metaanalysis including eight RCTs (n = 876) suggests a benefit of stenting before SWL in terms of steinstrasse formation, but does not result in a benefit on stone-free rates (SFRs) or less auxiliary treatments [122-124].

When steinstrasse is asymptomatic, conservative treatment is an initial option. Medical expulsion therapy significantly increases stone expulsion and reduces the need for endoscopic intervention [125, 126].

Summary of evidence	LE
Medical expulsion therapy increases the stone expulsion rate of steinstrasse [125].	1b
When spontaneous passage is unlikely, further treatment of steinstrasse is indicated.	4
Shock wave lithotripsy is indicated in asymptomatic and symptomatic cases, with no evidence of	4
urinary tract infection (UTI), when large stone fragments are present [127].	
Ureterenoscopy is effective for the treatment of steinstrasse [128].	3
Placement of a percutaneous nephrostomy tube or ureteral stent is indicated for symptomatic ureteric	4
obstruction with/without urinary tract infection.	

Recommendations	LE	GR
Treat steinstrasse associated with urinary tract infection/fever preferably with percutaneous	4	С
nephrostomy.		
Treat steinstrasse when large stone fragments are present with shock wave lithotripsy or	4	С
ureterorenoscopy.		

3.4.2 Specific stone management in renal stones

The natural history of small, non-obstructing asymptomatic calculi is not well defined, and the risk of progression is unclear. There is still no consensus on the follow-up duration, timing and type of intervention. Treatment options are chemolysis or active stone removal.

3.4.2.1 Types of treatments

3.4.2.1.1 Conservative treatment (Observation)

Observation of renal stones, especially in calices, depends on their natural history (Section 3.4.2.2). The recommendations provided are not supported by high level literature. There is a prospective trial supporting annual observation for asymptomatic inferior calyceal stones, \leq 10 mm. In case stone growth is detected the follow up interval should be lowered. Intervention is advised for stones growing > 5 mm [129].

Summary of evidence	LE
It is still debatable whether renal stones should be treated, or whether annual follow-up is sufficient for	4
asymptomatic calyceal stones that have remained stable for six months.	

Recommendation	GR
Follow-up periodically in cases where renal stones are not treated (initially after six months then yearly,	A*
evaluating symptoms and stone status [either by ultrasound, kidney-ureter-bladder radiography or	
computed tomographyl).	

*Upgraded based on panel consensus.

3.4.2.1.2 Chemolysis

3.4.2.1.2.1 Percutaneous irrigation chemolysis

Percutaneous chemolysis is rarely used nowadays. Percutaneous irrigation chemolysis may be an option for infection- and uric acid stones [130, 131]. For dissolution of struvite stones, Suby's G solution (10% hemiacidrin; pH 3.5-4) can be used [132].

3.4.2.1.2.2 Oral chemolysis

Stones composed of uric acid, but not sodium or ammonium urate, can be dissolved by oral chemolysis. Prior stone analysis may provide information on stone composition. Urinary pH measurement and X-ray characteristics can provide information on the type of stone.

Oral chemolitholysis is based on alkalinisation of urine by application of alkaline citrate or sodium bicarbonate [131, 133]. The pH should be adjusted to 7.0-7.2. Chemolysis is more effective at a higher pH, which might, however, promote calcium phosphate stone formation. Monitoring of radiolucent stones during therapy is the domain of US; however, repeat-NCCT might be necessary.

In the case of uric acid obstruction of the collecting system, oral chemolysis in combination with urinary drainage is indicated [134]. A combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage of distal ureteral uric acid stones [134].

ł
ł
\ *
ł
1

*Upgraded based on panel consensus.

3.4.2.1.3 Extracorporeal shock wave lithotripsy (SWL)

- Success depends on the efficacy of the lithotripter and the following factors:
- size, location (ureteral, pelvic or calyceal), and composition (hardness) of the stones (Section 3.4.3.2);
- patient's habitus (Section 3.4.2.2);
- performance of SWL (best practice, see below).

Each of these factors significantly influence retreatment rate and final outcome of SWL.

3.4.2.1.3.1 Contraindications of extracorporeal shock wave lithotripsy

There are several contraindications to the use of extracorporeal SWL, including:

- pregnancy, due to the potential effects on the foetus [135];
- bleeding diatheses, which should be compensated for at least 24 hours before and 48 hours after treatment [136];
- uncontrolled UTIs;

- severe skeletal malformations and severe obesity, which prevent targeting of the stone;
- arterial aneurysm in the vicinity of the stone [137];
- anatomical obstruction distal to the stone.

3.4.2.1.3.2 Best clinical practice

Stenting

Routine use of internal stents before SWL does not improve SFRs, nor lowers the number of auxiliary treatments. It may, however, reduce formation of steinstrasse [122, 124] (LE: 1b).

Pacemaker

Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken; patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters [138].

Shock wave rate

Lowering shock wave frequency from 120 to 60-90 shock waves/min improves SFRs [139-144]. Tissue damage increases with shock wave frequency [145-150].

Number of shock waves, energy setting and repeat treatment sessions

The number of shock waves that can be delivered at each session depends on the type of lithotripter and shock wave power. There is no consensus on the maximum number of shock waves.

Starting SWL on a lower energy setting with stepwise power (and SWL sequence) ramping can achieve vasoconstriction during treatment [147], which prevents renal injury [151-153]. Animal studies [154] and a prospective randomised study [155] have shown better SFRs (96% vs. 72%) using stepwise power ramping, but no difference has been found for fragmentation or evidence of complications after SWL, irrespective of whether ramping was used [156].

There are no conclusive data on the intervals required between repeated SWL sessions. However, clinical experience indicates that repeat sessions are feasible (within 1 day for ureteral stones).

Summary of evidence	LE
Stepwise power ramping prevents renal injury.	1b
Clinical experience has shown that repeat sessions are feasible (within one day for ureteral stones).	4
Optimal shock wave frequency is 1.0 to 1.5Hz.	1a

Improvement of acoustic coupling

Proper acoustic coupling between the cushion of the treatment head and the patient's skin is important. Defects (air pockets) in the coupling gel deflect 99% of shock waves [157]. Ultrasound gel is probably the most widely used agent available for use as a lithotripsy coupling agent [158].

Recommendation	LE	GR
Ensure correct use of the coupling agent because this is crucial for effective shock wave	2a	В
transportation.		

Procedural control

Results of treatment are operator dependent, and better results are obtained by experienced clinicians. During the procedure, careful imaging control of localisation contributes to outcome quality [159].

Recommendation	LE	GR
Maintain careful fluoroscopic and/or ultrasonographic monitoring during shock wave lithotripsy.	3	A*
*Upgraded based on panel consensus.		

Pain control

Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions [160-162].

Recommendation	LE	GR
Use proper analgesia because it improves treatment results by limiting pain-induced	4	С
movements and excessive respiratory excursions.		

Antibiotic prophylaxis

No standard antibiotic prophylaxis before SWL is recommended. However, prophylaxis is recommended in the case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g., indwelling catheter, nephrostomy tube, or infectious stones) [50, 163, 164].

Recommendation	LE	GR
In the case of infected stones or bacteriuria, prescribe antibiotics prior to shock wave	4	С
lithotripsy.		

Medical therapy after extracorporeal shock wave lithotripsy

In spite of conflicting results, most RCTs and several meta-analyses support MET after SWL for ureteral or renal stones as adjunct to expedite expulsion and to increase SFRs. Medical expulsion therapy might also reduce analgesic requirements [165-172].

3.4.2.1.3.3 Complications of extracorporeal shock wave lithotripsy

Compared to PNL and URS, there are fewer overall complications with SWL [173, 174] (Table 3.4.1).

Table 3.4.1: Shock wave lithotripsy-related complications [120, 175-188]

Complications			%	Ref.
Related to stone	Steinstrasse		4 - 7	[120, 175, 176]
fragments	Regrowth of residual		21 - 59	[177, 178]
	fragments			
	Renal colic		2 - 4	[179]
Infectious	Bacteriuria in non-		7.7 - 23	[177, 180]
	infection stones			
	Sepsis		1 - 2.7	[177, 180]
Tissue effect	Renal	Haematoma, symptomatic	< 1	[181]
		Haematoma, asymptomatic	4 - 19	[181]
	Cardiovascular	Dysrhythmia	11 - 59	[177, 182]
		Morbid cardiac events	Case reports	[177, 182]
	Gastrointestinal	Bowel perforation	Case reports	[183-185]
		Liver, spleen haematoma	Case reports	[15-188]

The relationship between SWL and hypertension or diabetes is unclear. Published data are contradictory; however, no evidence exists supporting the hypothesis that SWL may cause long-term adverse effects [189-194].

3.4.2.1.4 Endourology techniques for renal stone removal

3.4.2.1.4.1 Percutaneous nephrolithotomy (PNL)

Percutaneous nephrolithotripsy remains the standard procedure for large renal calculi. Different rigid and flexible endoscopes are available and the selection is mainly based on the surgeon's own preference. Standard access tracts are 24-30 F. Smaller access sheaths, < 18 French, were initially introduced for paediatric use, but are now increasingly popular in adults.

The efficacy of miniaturised systems seems to be high, but longer operation times apply and benefit compared to standard PNL for selected patients has yet to be demonstrated [195]. There is some evidence that smaller tracts cause less bleeding complications, but further studies need to evaluate this issue. Smaller instruments bear the risk of increasing intra-renal pelvic pressure [5, 196-198].

3.4.2.1.4.1.1 Contraindications

Patients receiving anticoagulant therapy must be monitored carefully pre- and post-operatively. Anticoagulant therapy must be discontinued before PNL [112].

Other important contraindications include:

untreated UTI;

- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.3.1).

3.4.2.1.4.1.2 Best clinical practice

Intracorporeal lithotripsy

Several methods for intracorporeal lithotripsy are available (devices are discussed in Section 3.4.1.2.1.1.5). During PNL, ultrasonic and pneumatic systems are most commonly used for rigid nephroscopy. When using miniaturised instruments, laser lithotripsy is associated with lower stone migration than with pneumatic lithotripsy [199]. Flexible endoscopes require laser lithotripsy to maintain tip deflection and the Ho:YAG laser has become the standard [200].

Recommendation	GR
Use ultrasonic, ballistic and holmium: yttrium-aluminium-garnet devices for intracorporeal lithotripsy	A*
during percutaneous nephrolithotomy.	

*Upgraded based on panel consensus.

Pre-operative imaging

Pre-procedural evaluations are summarised in Section 3.3.1. In particular, PNL, US or CT of the kidney and the surrounding structures can provide information regarding interpositioned organs within the planned percutaneous path (e.g., spleen, liver, large bowel, pleura, and lung) [201].

Recommendation	GR
Perform pre-procedural imaging, including contrast medium where possible or retrograde study when	A*
starting the procedure, to assess stone comprehensiveness and anatomy of the collecting system to	
ensure safe access to the renal stone	

*Upgraded based on panel consensus.

For antibiotic therapy - see General recommendations and precautions for stone removal (Section 3.4.1.4.1).

Positioning of the patient

Both prone and supine positions are equally safe.

Although the supine position confers some advantages, it depends on appropriate equipment being available to position the patient correctly, for example, X-ray devices and an operating table. Most studies cannot demonstrate an advantage of supine PNL in terms of operating room (OR) time. In some series, SFR is lower than for the prone position despite a longer OR time. Prone position offers more options for puncture and is therefore preferred for upper pole or multiple access [202-204]. On the other hand, supine position allows simultaneous retrograde access to the collecting system, using flexible ureteroscope [205]. The Urolithiasis Guidelines Panel aim to set up a SR to assess this topic.

Puncture

Although fluoroscopy is the most common intra-operative imaging method, the (additional) use of US reduces the radiation exposure.

Colon interposition in the access tract of PNL can lead to colon injuries. Pre-operative CT or intra-operative US allows identification of the tissue between the skin and kidney and lowers the incidence of bowel injury. The calyceal puncture may be done under direct visualisation using simultaneous flexible ureterenoscopy [206-209].

Dilatation

Dilatation of the percutaneous access tract can be achieved using a metallic telescope, single (serial) dilators, or a balloon dilatator. Although there are papers demonstrating that single step dilation is equally effective as other methods, the difference in outcomes is most likely related to surgeon experience rather than to the technology used [210].

Choice of instruments

The Urolithiasis Panel performed a SR assessing the outcomes of PNL using smaller tract sizes (< 22 Fr, mini-PNL) for removing renal calculi [5]. Stone-free rates were comparable in miniaturised and standard PNL

procedures. Procedures performed with small instruments tended to be associated with significantly lower blood loss, while the duration of procedure tended to be significantly longer. Other complications were not notably different between PNL types. However, the quality of the evidence was poor, drawn mainly from small studies, the majority of which were single-arm case series, and only two of which were RCTs. Furthermore, the tract sizes used, and types of stones treated were heterogeneous. Hence, the risk of bias and confounding were high.

Nephrostomy and stents

The decision on whether or not to place a nephrostomy tube at the end of the PNL procedure depends on several factors, including:

- presence of residual stones;
- likelihood of a second-look procedure;
- significant intra-operative blood loss;
- urine extravasation;
- ureteral obstruction;
- potential persistent bacteriuria due to infected stones;
- solitary kidney;
- bleeding diathesis;
- planned percutaneous chemolitholysis.

Small bore nephrostomies seem to have advantages in terms of post-operative pain [211, 212]. Tubeless PNL is performed without a nephrostomy tube. When neither a nephrostomy tube nor a ureteral stent is introduced, the procedure is known as totally tubeless PNL. In uncomplicated cases, the latter procedure results in a shorter hospital stay, with no disadvantages reported [213-215].

Recommendation	LE	GR
In uncomplicated cases, perform a tubeless (without nephrostomy tube) or totally tubeless	1b	A
(without nephrostomy tube and ureteral stent) percutaneous nephrolithotomy procedure as it is		
a safe alternative.		

3.4.2.1.4.1.3 Complications

The most common post-operative complications associated with PNL are fever and bleeding, urinary leakage, and problems due to residual stones (Table 3.4.2).

Table 3.4.2: Complications following percutaneous nephrolithotomy [216]

Complications	Trans-	Embolisation	Urinoma	Fever	Sepsis	Thoracic	Organ	Death	LE
	fusion					complication	injury		
(Range)	(0-20%)	(0-1.5%)	(0-1%)	(0-	(0.3-	(0-11.6%)	(0-	(0-	1a
				32.1%)	1.1%)		1.7%)	0.3%)	
N = 11,929	7%	0.4%	0.2%	10.8%	0.5%	1.5%	0.4%	0.05%	

Peri-operative fever can occur, even with a sterile pre-operative urinary culture and peri-operative antibiotic prophylaxis, because the renal stones themselves may be a source of infection. Intra-operative renal stone culture may therefore help to select post-operative antibiotics [217, 218]. Intra-operative irrigation pressure < 30 mmHg and unobstructed post-operative urinary drainage may be important factors in preventing post-operative sepsis. Bleeding after PNL may be treated by brief clamping of the nephrostomy tube. Super-selective embolic occlusion of the arterial branch may become necessary in the case of severe bleeding.

3.4.2.1.4.2 Ureterorenoscopy for renal stones (RIRS)

Technical improvements including endoscope miniaturisation, improved deflection mechanism, enhanced optical quality and tools, and introduction of disposables have led to an increased use of URS for both, renal and ureteral stones. Major technological progress has been achieved for RIRS. A recent SR addressing renal stones > 2 cm showed a cumulative SFR of 91% with 1.45 procedures/patient; 4.5% of the complications were \geq Clavien 3 [219-221]. Digital scopes demonstrate shorter operation times due to the improvement in image quality [220, 222, 223]. For best clinical practice see Section 3.4.3.1.4.1.2 - Ureteral stones-URS.

Stones that cannot be extracted directly must be disintegrated. If it is difficult to access stones that need disintegration within the lower renal pole, it may help to displace them into a more accessible calyx [224].

Recommendation	GR
Use flexible ureterorenoscopy in case percutaneous nephrolithotomy or shock wave lithotripsy are	В
not an option (even for stones > 2 cm). However, in that case there is a higher risk that a follow-up	
procedure and placement of a ureteral stent may be needed. In complex stone cases, use open or	
laparoscopic approaches as possible alternatives.	

3.4.2.1.4.3 Open and laparoscopic surgery for removal of renal stones

Advances in SWL and endourological surgery (URS and PNL) have significantly decreased the indications for open or laparoscopic stone surgery [225-231]. There is a consensus that most complex stones, including partial and complete staghorn stones, should be approached primarily with PNL. Additionally, a combined approach with PNL and RIRS may also be an appropriate alternative. However, if a reasonable number of percutaneous approaches are not likely to be successful, or if multiple, endourological approaches have been performed unsuccessfully; open or laparoscopic surgery may be a valid treatment option [232-239].

Recommendations	LE	GR
Offer laparoscopic or open surgical stone removal in rare cases in which shock wave	3	С
lithotripsy, (flexible) ureterorenoscopy and percutaneous nephrolithotomy fail, or are unlikely to		
be successful.		
When expertise is available, perform surgery laparoscopically before proceeding to open	3	С
surgery, especially when the stone mass is centrally located.		

3.4.2.2 Indication for active stone removal of renal stones [240]

- stone growth;
- stones in high-risk patients for stone formation;
- obstruction caused by stones;
- infection;
- symptomatic stones (e.g., pain or haematuria);
- stones > 15 mm;
- stones < 15 mm if observation is not the option of choice.
- patient preference;
- comorbidity;
- social situation of the patient (e.g., profession or travelling);
- choice of treatment.

The risk of a symptomatic episode or need for intervention of patients with asymptomatic renal stones seems to be ~10-25% per year, with a cumulative five-year event probability of 48.5% [129, 241, 242]. A prospective RCT with > 2 year clinical follow-up reported no significant difference between SWL and observation when comparing asymptomatic calyceal stones < 15 mm in terms of SFR, symptoms, requirement for additional treatment, quality of life (QoL), renal function, or hospital admission [243]. Although some have recommended prophylaxis for these stones to prevent renal colic, haematuria, infection, or stone growth, conflicting data have been reported [242, 244, 245]. In a follow-up period of almost five years after SWL, two series have demonstrated that up to 25% of patients with small residual fragments needed treatment [178, 246]. Although the question of whether calyceal stones should be treated is still unanswered, stone growth, *de novo* obstruction, associated infection, and acute and/or chronic pain are indications for treatment [240, 247, 248].

Summary of evidence	LE
Although the question of whether calyceal stones should be treated is still unanswered, stone growth,	3
de novo obstruction, associated infection, and acute and/or chronic pain are indications for treatment.	

Recommendations	GR
Offer active treatment for renal stones in case of stone growth, de novo obstruction, associated	С
infection, and acute and/or chronic pain.	
Assess comorbidity and patient preference when making treatment decisions.	С

3.4.2.3 Selection of procedure for active removal of renal stones

For general recommendations and precautions see Section 3.4.1.3.

3.4.2.3.1 Stones in renal pelvis or upper/middle calices

Shock wave lithotripsy, PNL and RIRS are available treatment modalities for renal calculi. While PNL efficacy is hardly affected by stone size, the SFRs after SWL or URS are inversely proportional to stone size [249-252]. Shock wave lithotripsy achieves good SFRs for stones up to 20 mm, except for those at the lower pole [251, 253, 254]. Endourology is considered an alternative because of the reduced need of repeated procedures and consequently a shorter time until stone-free status is achieved. Stones > 20 mm should be treated primarily by PNL, because SWL often requires multiple treatments, and is associated with an increased risk of ureteral obstruction (colic or steinstrasse) with a need for adjunctive procedures (Figure 3.4.1) [173]. Retrograde renal surgery cannot be recommended as first-line treatment for stones > 20 mm in uncomplicated cases as SFRs decrease, and staged procedures will be required [255-257]. However, it may be a first-line option in patients where PNL is not an option or contraindicated.

3.4.2.3.2 Stones in the lower renal pole

The stone clearance rate after SWL seems to be lower for stones in the inferior calyx than for other intra-renal locations. Although the disintegration efficacy of SWL is not limited compared to other locations, the fragments often remain in the calyx and cause recurrent stone formation. The reported SFR of SWL for lower pole calculi is 25-95%. The preferential use of endoscopic procedures is supported by some current reports, even for stones smaller than 1 cm [173, 249, 250, 252, 253, 257-265].

The following can impair successful stone treatment by SWL [260, 266-269]:

- steep infundibular-pelvic angle;
- long calyx;
- long skin-to-stone distance;
- narrow infundibulum (Table 3.4.4).

Further anatomical parameters cannot yet be established. Supportive measures such as inversion, vibration or hydration may facilitate stone clearance [270].

Table 3.4.4: Unfavourable factors for shock wave lithotripsy success for lower calyceal stones [260, 266, 271]

Factors that make shock wave lithotripsy less likely
Shock wave-resistant stones (calcium oxalate monohydrate, brushite, or cystine).
Steep infundibular-pelvic angle.
Long lower pole calyx (> 10 mm).
Narrow infundibulum (< 5 mm).
Long skin-to-stone distance (> 10 cm).

If there are negative predictors for SWL, PNL and RIRS might be reasonable alternatives, even for smaller calculi [258]. Retrograde renal surgery seems to have comparable efficacy to SWL [173, 253]. Recent clinical experience has suggested a higher SFR of RIRS compared to SWL, but at the expense of greater invasiveness. Depending on operator skills, stones up to 3 cm can be treated by RIRS [221, 272-274]. However, staged procedures are frequently required.

In complex stone cases, open or laparoscopic approaches are possible alternatives (see appropriate chapters).

3.4.2.3.3 Recommendations for the selection of procedures for active removal of renal stones

Recommendations	GR
Offer shock wave lithotripsy (SWL) and endourology (percutaneous nephrolithotomy [PNL], retrograde	В
renal surgery [RIRS]) as treatment options for stones < 2 cm within the renal pelvis and upper or	
middle calices.	
Perform PNL as first-line treatment of larger stones > 2 cm.	В
In case PNL is not an option, treat larger stones (> 2 cm) with flexible ureterorenoscopy or SWL.	В
However, in such instances there is a higher risk that a follow-up procedure and placement of a	
ureteral stent may be needed.	
For the lower pole, perform PNL or RIRS, even for stones > 1 cm, as the efficacy of SWL is limited	В
(depending on favourable and unfavourable factors for SWL).	

Figure 3.4.1: Treatment algorithm for renal calculi

*The term 'Endourology' encompasses all PNL and URS interventions.

PNL = percutaneous nephrolithotomy; RIRS = retrograde renal surgery; SWL = shock wave lithotripsy; URS = ureterorenoscopy.

3.4.3 Specific stone management of Ureteral stones

3.4.3.1 Types of treatment

3.4.3.1.1 Conservative treatment/observation

There are only limited data regarding spontaneous stone passage according to stone size [275]. It is estimated that 95% of stones up to 4 mm pass within 40 days [189].

Observation is feasible in informed patients who develop no complications (infection, refractory pain, deterioration of renal function).

Recommendations	LE	GR
In patients with newly diagnosed small* ureteral stones, if active removal is not indicated	1a	А
(Section 3.4.2.2), observe patient initially with periodic evaluation.		
Offer patient appropriate medical therapy to facilitate stone passage during observation.		

*See stratification data [189].

Based on the analysis of available evidence, an exact cut-off size for stones that are likely to pass spontaneously cannot be provided; < 10 mm may be considered a best estimate [189]. Therefore, the Panel decided not to include stone size but rather recommend "small", suggesting < 6 mm. The Panel is aware of the fact that spontaneous stone expulsion decreases with increasing stone size and that there are differences between individual patients.

3.4.3.1.2 Pharmacological treatment, Medical expulsive therapy

Medical expulsive therapy (MET) should only be used in informed patients. Treatment should be discontinued if complications develop (infection, refractory pain, deterioration of renal function). Several substances are in discussion for MET [276-279]. When using α -blockers for MET possible side effects include retrograde ejaculation and hypotension [84].

Meta-analyses have shown that patients with ureteral stones treated with α -blockers or nifedipine are more likely to pass stones with fewer colic episodes than those not receiving such therapy [84, 280]. However, there is contradictory evidence between these studies and several well-designed, multicentre, placebo-controlled, double-blinded randomised studies showing limited, or no, benefit using α -blockers, besides some advantage for distal ureteral stones > 5 mm) [87, 88, 281]. A published meta-analysis, including 55 trials with a data search cut-off of July 1st 2015, also including the publications addressed above, assessed stone passage as primary outcome [4]. Based on the well-designed sensitivity analyses of this meta-analysis, α -blockers promote spontaneous stone expulsion of large stones located in any part of the ureter.

The panel concludes that MET seems efficacious in the treatment of patients with ureteric stones who are amenable to conservative management. The greatest benefit might be among those with larger (distal) stones [282].

Summary of evidence	LE
MET seems to be efficacious treating patients with ureteric stones who are amenable to conservative	1a
management. The greatest benefit might be among those with larger (distal) stones.	

Based on studies with a limited number of patients [279, 283, 284] (LE: 1b), no recommendation for the use of corticosteroids in combination with α -blockers in MET can be made.

Summary of evidence	LE
There is no evidence to support the use of corticosteroids as monotherapy for MET.	1b
Insufficient data exist to support the use of corticosteroids in combination with α -blockers as an accelerating adjunct.	2a

Recommendations	LE	GR
Select patients for an attempt at spontaneous passage or medical expulsive therapy (MET),	4	С
based on well-controlled pain, no clinical evidence of sepsis, and adequate renal functional		
reserve.		
Offer α -blockers as MET as one of the treatment options, in particular for (distal) ureteral	1a	А
stones > 5 mm.		
Counsel patients regarding the controversies in the literature, attendant risks of MET, including	1b	A*
associated drug side effects. Inform the patient that α -blockers as MET are administered off-		
label [†] **.		
Follow-up patients in short intervals to monitor stone position and assess for hydronephrosis.	4	A*

^{*†*} It is not known if tamsulosin harms the human foetus or if it is found in breast milk.

*Upgraded based on panel consensus.

**MET in children cannot be recommended due to the limited data in this specific population.

Medical expulsive therapy in special situations is addressed in the particular chapters

3.4.3.1.2.1 Duration of medical expulsive therapy treatment

Most studies have had a duration of one month. No data are currently available to support other time-intervals.

3.4.3.1.3 Shock wave lithotripsy

For best clinical practice, see Section 3.4.2.1.4.1.2 (Renal stones).

Stenting

The stenting is not recommended as part of SWL, since it does not increase SFRs [189, 285]. When a stent is inserted, patients often suffer from frequency, dysuria, urgency, and suprapubic pain [285].

Recommendation	LE	GR
Do no routinely use a stent as part of shock wave lithotripsy treatment of ureteral stones.	1b	А

3.4.3.1.4 Endourology techniques

3.4.3.1.4.1 Ureterorenoscopy

The current standard for rigid ureterorenoscopes are tip diameters of < 8 F. Rigid URS can be used for the whole ureter [189]. However, technical improvements, as well as the availability of digital scopes also favour the use of flexible ureteroscopes in the ureter [219].

3.4.3.1.4.1.1 Contraindications

Apart from general problems, for example, with general anaesthesia or untreated UTIs, URS can be performed in all patients without any specific contraindications.

3.4.3.1.4.1.2 Best clinical practice in ureterorenoscopy (URS)

Access to the upper urinary tract

Most interventions are performed under general anaesthesia, although local or spinal anaesthesia is possible. Intravenous sedation is suitable for female patients with distal ureteral stones [286].

Antegrade URS is an option for large, impacted proximal ureteral calculi [287] (Section 3.4.3.1.4.2).

Safety aspects

Fluoroscopic equipment must be available in the OR. We recommend placement of a safety wire, even though some groups have demonstrated that URS can be performed without it [288-290].

Balloon and plastic dilators should be available, if necessary.

Prior rigid ureterenoscopy can be helpful for optical dilatation followed by flexible URS, if necessary. If ureteral access is not possible, insertion of a JJ stent followed by URS after seven to fourteen days offers an alternative procedure. Bilateral URS during the same session is feasible resulting in similar SFRs, but slightly higher overall (mostly minor) complication rates [291].

Ureteral access sheaths

Hydrophilic-coated ureteral access sheaths, which are available in different calibres (inner diameter from 9 F upwards), can be inserted via a guide wire, with the tip placed in the proximal ureter.

Ureteral access sheaths allow easy, multiple, access to the upper urinary tract and therefore significantly facilitate URS. The use of ureteral access sheaths improves vision by establishing a continuous outflow, decreasing intra-renal pressure, and potentially reduces operating time [292, 293].

The insertion of ureteral access sheaths may lead to ureteral damage, whereas the risk is lowest in pre-stented systems [294]. No data on long-term side effects are available [294, 295]. Use of ureteral access sheaths depends on the surgeon's preference.

Stone extraction

The aim of URS is complete stone removal. "Dust and go" strategies should be limited to the treatment of large (renal) stones.

Stones can be extracted by endoscopic forceps or baskets. Only baskets made of nitinol can be used for flexible URS [296].

Recommendation	LE	GR
Do not perform stone extraction using a basket without endoscopic visualisation of the stone	4	A*
(blind basketing).		

*Upgraded based on panel consensus.

Intracorporeal lithotripsy

The most effective lithotripsy system is the Ho:YAG laser, which is currently the optimum standard for ureterenoscopy and flexible nephroscopy (Section 3.4.2.1.4.1.2), because it is effective in all stone types [297, 298]. Pneumatic and US systems can be used with high disintegration efficacy in rigid URS [299, 300].

However, stone migration into the kidney is a common problem, which can be prevented by placement of special anti-migration tools proximal of the stone [301]. Medical expulsion therapy following Ho:YAG laser lithotripsy increases SFRs and reduces colic episodes [302] (LE: 1b).

Recommendation	LE	GR
Use holmium: yttrium-aluminium-garnet laser lithotripsy for (flexible) ureterorenoscopy.	3	В

Stenting before and after URS

Routine stenting is not necessary before URS. However, pre-stenting facilitates ureteroscopic management of stones, improves the SFR, and reduces intra-operative complications [303, 304].

Randomised prospective trials have found that routine stenting after uncomplicated URS (complete stone removal) is not necessary; stenting might be associated with higher post-operative morbidity [305-307]. A ureteric catheter with a shorter indwelling time (one day) may also be used, with similar results [308].

Stents should be inserted in patients who are at increased risk of complications (e.g., ureteral trauma, residual fragments, bleeding, perforation, UTIs, or pregnancy), and in all doubtful cases, to avoid stressful emergencies. The ideal duration of stenting is not known. Most urologists favour 1-2 weeks after URS. Alpha-blockers reduce the morbidity of ureteral stents and increase tolerability [309, 310]. A recently published meta-analysis provides evidence for improvement of ureteral stent tolerability with tamsulosin [311].

Medical expulsive therapy after ureterenoscopy

Medical expulsion therapy following Ho:YAG laser lithotripsy accelerates the spontaneous passage of fragments and reduces episodes of colic [302] (LE: 1b).

Summary of evidence	LE
In uncomplicated ureterorenoscopy (URS), a stent need not be inserted.	1a
In URS (in particular for renal stones), pre-stenting has been shown to improve outcome.	1b
An α -blocker can reduce stent-related symptoms and colic episodes.	1b

3.4.3.1.4.1.3 Complications

The overall complication rate after URS is 9-25% [189, 312, 313]. Most are minor and do not require intervention. Ureteral avulsion and strictures are rare (< 1%). Previous perforations are the most important risk factor for complications.

3.4.3.1.4.2 Percutaneous antegrade ureterenoscopy

Percutaneous antegrade removal of ureteral stones is a consideration in selected cases, i.e. large, impacted proximal ureteral calculi with dilated renal collecting system [314], or when the ureter is not amenable to retrograde manipulation [287, 315-318].

Recommendation	GR
Use percutaneous antegrade removal of ureteral stones as an alternative when shock wave lithotripsy	A
is not indicated or has failed, and when the upper urinary tract is not amenable to retrograde	
ureterorenoscopy.	

3.4.3.1.5 Laparoscopic ureteral stone removal

Few studies have reported laparoscopic stone removal (Section 3.4.2.1.4.3). These procedures are usually reserved for special cases. When expertise is available, laparoscopic ureterolithotomy can be performed for large proximal ureteral stones as an alternative to URS or SWL [319, 320]. These more invasive procedures have yielded high SFRs and lower auxiliary procedure rates [234].

Recommendation	LE	GR
For ureterolithotomy, perform laparoscopy for large impacted stones when endoscopic	2	В
lithotripsy or shock wave lithotripsy has failed.		

3.4.3.2 Indications for active removal of ureteral stones [189, 275, 321]

Indications for active removal of ureteral stones are:

- stones with a low likelihood of spontaneous passage;
- persistent pain despite adequate analgesic medication;
- persistent obstruction;
- renal insufficiency (renal failure, bilateral obstruction, or single kidney).

For general recommendations and precautions see Section 3.4.1.3. Obesity can cause a lower success rate after SWL and PNL and may influence the choice of treatment.

Summary of evidence	LE
In the case of severe obesity, ureterorenoscopy is a more promising therapeutic option than shock	2b
wave lithotripsy.	

3.4.3.2.5.1 Bleeding disorder

Ureterorenoscopy can be performed in patients with bleeding disorders, with a moderate increase in complications (see also Section 3.4.1.3) [112, 115].

3.4.3.3 Selection of procedure for active removal of ureteral stones

Overall SFRs after URS or SWL for ureteral stones are comparable. However, larger stones achieve earlier stone-free status with URS. Although URS is effective for ureteric calculi, it has greater potential for complications. However, in the current endourological era, the complication rate and morbidity of ureterenoscopy have been significantly reduced [322]. It has been demonstrated that URS is a safe option in obese patients (BMI > 30 kg/m^2) with comparable SFRs and complication rates. However, in morbidly obese patients (BMI > 35 kg/m^2) the overall complication rates double [323].

The Panel performed an SR to assess the benefits and harms of URS compared to SWL [6]. Compared with SWL, URS was associated with a significantly greater SFR up to four weeks, but the difference was not significant at three months in the included studies. Ureterorenoscopy was associated with fewer re-treatments and need for secondary procedures, but with a higher need for adjunctive procedures, greater complication rates and longer hospital stay. Counterbalancing for URS's higher SFRs, SWL is associated with least morbidity. Clavien-Dindo grade complications were, if reported, less frequent in patients treated with SWL.

*Upgraded following panel consensus.

SWL = shock wave lithotripsy; URS = ureterenoscopy.

Summary of evidence	LE
In obese patients ureterorenoscopy (URS) is a safe and efficient option to remove renal stones.	2b
Ureterorenoscopy in morbidly obese patients have significantly higher complication rates as compared	1a
to normal weight patients.	

Recommendations	GR
Inform patients that ureterorenoscopy (URS) has a better chance of achieving stone-free status with a	А
single procedure.	
Inform patients that URS has higher complication rate when compared to shock wave lithotripsy.	А

3.4.4 Management of patients with residual stones

The clinical problem of residual renal stones is related to the risk of developing:

- new stones from such nidi (heterogeneous nucleation);
- persistent UTI;
- dislocation of fragments with/without obstruction and symptoms [178, 324, 325].

Recommendations	LE	GR
Identify biochemical risk factors and offer appropriate stone prevention to patients with		А
residual fragments or stones [178, 325, 326].		
Follow-up patients with residual fragments or stones regularly to monitor disease course.	4	С

Recurrence risk in patients with residual fragments after treatment of infection stones is higher than for other stones [326]. For all stone compositions, 21-59% of patients with residual stones required treatment within five years. Fragments > 5 mm are more likely than smaller ones to require intervention [178, 324, 327]. There is evidence that fragments > 2 mm are more likely to grow, although this is not associated with increased re-intervention rates at one year follow up [328].

3.4.4.1 Therapy

The indications for active removal of residual stones and selection of the procedure are based on the same criteria as for primary stone treatment (Section 3.4.2.4) and includes repeat SWL [329].

If intervention is not required, medical therapy according to stone analysis, patient risk group, and metabolic evaluation might help to prevent regrowth of residual fragments [330-332].

Summary of evidence	LE
For well-disintegrated stone material in the lower calix, an inversion therapy with simultaneous	1b
mechanical percussion manoeuvre under enforced diuresis may facilitate stone clearance [270].	

Recommendation	LE	GR
After shock wave lithotripsy and ureteronoscopy, and in the presence of residual fragments,	1a	А
offer medical expulsive therapy using an α -blocker to improve fragment clearance.		

Table 3.4.5: Recommendations for the treatment of residual fragments

Residual fragments, stones	Symptomatic residuals	Asymptomatic residuals	LE	GR
(largest diameter)				
< 4-5 mm	Stone removal	Reasonable follow-up	4	С
		(dependent on risk factors)		
> 5 mm	Stone removal		4	С

3.4.5 Management of specific patient groups

3.4.5.1 Management of urinary stones and related problems during pregnancy

Clinical management of a pregnant urolithiasis patient is complex and demands close collaboration between patient, radiologist, obstetrician and urologist. For diagnostic imaging see Section 3.3.1.

If spontaneous passage does not occur, or if complications develop (e.g., induction of premature labour), placement of a ureteral stent or a percutaneous nephrostomy tube is necessary [333-335]. Unfortunately, these

temporising therapies are often associated with poor tolerance, and they require multiple exchanges during pregnancy, due to the potential for rapid encrustation. Ureterenoscopy has become a reasonable alternative in these situations [336-338]. Although feasible, retrograde endoscopic and percutaneous removal of renal stones during pregnancy remain an individual decision and should be performed only in experienced centres [339].

Pregnancy remains an absolute contraindication for SWL.

Summary of evidence	LE
If intervention becomes necessary, placement of a ureteral stent or a percutaneous nephrostomy tube	3
is a readily available primary option.	
Ureterenoscopy is a reasonable alternative to avoid long-term stenting/drainage.	1a
Regular follow-up until final stone removal is necessary due to the higher encrustation tendency of	
stents during pregnancy.	

Recommendation	GR
Treat all uncomplicated cases of urolithiasis in pregnancy conservatively (except those that have	А
clinical indications for intervention).	

3.4.5.2 Management of stones in patients with urinary diversion

3.4.5.2.1 Aetiology

Patients with urinary diversion are at high risk for stone formation in the renal collecting system and ureter or in the conduit or continent reservoir [340-342]. Metabolic factors (hypercalciuria, hyperoxaluria and hypocitraturia), infection with urease-producing bacteria, foreign bodies, mucus secretion, and urinary stasis are responsible for stone formation [343] (Section 3.1.3). One study has shown that the risk for recurrent upper-tract stones in patients with urinary diversion subjected to PNL was 63% at five years [344].

3.4.5.2.2 Management

Smaller upper-tract stones can be treated effectively with SWL [316, 345]. In the majority, endourological techniques are necessary to achieve stone-free status [315]. In individuals with long, tortuous conduits or with invisible ureter orifices, a retrograde endoscopic approach might be difficult or impossible.

Summary of evidence	LE
The choice of access depends on the feasibility of orifice identification in the conduit or bowel	4
reservoir. Whenever a retrograde approach is impossible, percutaneous access with antegrade	
ureterorenoscopy is the alternative.	

Recommendation	GR
Perform percutaneous lithotomy to remove large renal stones in patients with urinary diversion, as well	A*
as for ureteral stones that cannot be accessed via a retrograde approach, or that are not amenable to	
shock wave lithotripsy.	

For stones in the conduit, a trans-stomal approach can be used to remove all stone material (along with the foreign body) using standard techniques, including intracorporeal lithotripsy and flexible endoscopes. Transstomal manipulations in continent urinary diversion must be performed carefully to avoid disturbance of the continence mechanism [346].

Before considering any percutaneous approach in these cases, CT should be undertaken to assess the presence of an overlying bowel, which could make this approach unsafe [347], and if present, an open surgical approach should be considered.

3.4.5.2.3 Prevention

Recurrence risk is high in these patients [344]. Metabolic evaluation and close follow-up are necessary to obtain the risk parameters for effective long-term prevention. Preventive measures include medical management of metabolic abnormalities, appropriate therapy of urinary infections, and hyperdiuresis or regular irrigation of continent reservoirs [348].

3.4.5.3 Management of stones in patients with neurogenic bladder

3.4.5.3.1 Aetiology, clinical presentation and diagnosis

Patients with neurogenic bladder develop urinary calculi because of additional risk factors such as bacteriuria, pelvicaliectasis, VUR, renal scarring, lower urinary tract reconstruction, and thoracic spinal defect [349]. The most common causes are urinary stasis and infection (Section 3.1.3). Indwelling catheters and surgical interposition of bowel segments for treatment of bladder dysfunction both facilitate UTI. Although calculi can form at any level of the urinary tract, they occur more frequently in the bladder; especially if bladder augmentation has been performed [350, 351].

Diagnosis of stones may be difficult and delayed in the absence of clinical symptoms due to sensory impairment and vesicourethral dysfunction. Difficulties in self-catheterisation should lead to suspicion of bladder calculi. Imaging studies are needed (US, CT) to confirm the clinical diagnosis prior to surgical intervention.

3.4.5.3.2 Management

Management of calculi in patients with neurogenic bladder is similar to that described in Section 3.3.3. In MMC (myelomeningocele) patients, latex allergy is common, therefore, appropriate measures need to be taken regardless of the treatment [352]. Any surgery in these patients must be performed under general anaesthesia because of the impossibility of using spinal anaesthesia. Bone deformities often complicate positioning on the operating table [353]. The risk of stone formation after augmentation cystoplasty in immobile patients with sensory impairment can be significantly reduced by irrigation protocols [348].

For efficient long-term stone prevention in patients with neurogenic bladder, correction of the metabolic disorder, appropriate infection control, and restoration of normal storing/voiding function of the bladder are needed.

Summary of evidence	LE
Patients undergoing urinary diversion and/or suffering from neurogenic bladder dysfunction are at risk	3
for recurrent stone formation.	

Recommendation	GR
Take appropriate measures regardless of the treatment provided since in myelomeningocele patients	В
latex allergy is common.	

3.4.5.4 Management of stones in transplanted kidneys

3.4.5.4.1 Aetiology

Transplant patients depend on their solitary kidney for renal function. Impairment causing urinary stasis/ obstruction therefore requires immediate intervention or drainage of the transplanted kidney. Risk factors in these patients are multifold:

- immunosuppression increases the infection risk, resulting in recurrent UTIs;
- hyper filtration, excessively alkaline urine, renal tubular acidosis, and increased serum calcium caused by persistent tertiary hyperparathyroidism [354] are biochemical risk factors.

Stones in kidney allografts have an incidence of 0.2-1.7% [355-357].

Recommendation	LE	GR
Perform ultrasound or non-contrast-enhanced computed tomography to rule out calculi		В
in patients with transplanted kidneys, unexplained fever, or unexplained failure to thrive		
(particularly in children) [358].		

3.4.5.4.2 Management

Selecting the appropriate technique for stone removal in a transplanted kidney is difficult, although management principles are similar to those applied in other single renal units [359-362]. Additional factors such as transplant function, coagulative status, and anatomical obstacles due to the iliacal position of the organ, directly influence the surgical strategy.

For large or ureteral stones, careful percutaneous access and subsequent antegrade endoscopy are more favourable. The introduction of small flexible ureteroscopes and the holmium laser has made ureterenoscopy a valid treatment option for transplant calculi. However, one must be aware of potential injury to adjacent organs [363-365]. Retrograde access to transplanted kidneys is difficult due to the anterior location of the ureteral anastomosis, and ureteral tortuosity [366-368].

Summary of evidence	LE
Conservative treatment for small asymptomatic stones is only possible under close surveillance and in	
absolutely compliant patients.	
Shock wave lithotripsy for small calyceal stones is an option with minimal complication risk, but	4
localisation of the stone can be challenging and stone-free rates are poor [369, 370].	

Recommendations	GR
Offer patients with transplanted kidneys, any of the contemporary management options, including	В
shock wave therapy, flexible ureterenoscopy and percutaneous nephrolithotomy.	
Complete metabolic evaluation after stone removal.	A*

*Upgraded following panel consensus.

3.4.5.4.3 Special problems in stone removal

Table 3.4.6: Special problems in stone removal

Calyceal diverticulum stones	 Shock wave lithotripsy (SWL), percutaneous nephrolithotomy (PNL) (if possible) or retrograde renal surgery (RIRS). Can also be removed using laparoscopic retroperitoneal surgery [371-375]. Patients may become asymptomatic due to stone disintegration (SWL), whilst well-disintegrated stone material remains in the original position due to narrow calyceal neck.
Horseshoe kidneys	Can be treated in line with the options described above [376].
	 Passage of fragments after SWL might be poor.
	Acceptable SFRs can be achieved with flexible ureteroscopy [377].
Stones in pelvic kidneys	SWL, RIRS, PNL or laparoscopic surgery.
	In obese patients, the options are RIRS, PNL or open surgery.
Stones formed in a	• See Section 3.4.4.
continent reservoir	Each stone must be considered and treated individually.
Patients with obstruction of	• When outflow abnormality requires correction, stones can be removed by
the ureteropelvic junction	PNL together with percutaneous endopyelotomy or open/laparoscopic reconstructive surgery.
	Ureterorenoscopy together with endopyelotomy with holmium: yttrium- aluminium-garnet laser.
	• Incision with an Acucise [®] balloon catheter might be considered, provided
	the stones can be prevented from falling into the pelvi-ureteral incision [378-381].
	 Open surgery with correction of the UPJ obstruction (pyeloplasty) and stone removal is a feasible option [382].

3.4.6 Management of urolithiasis in children

Rates of urolithiasis have increased in developed countries, and there has been a shift in the age group experiencing a first stone episode [10, 383, 384]. More than 1% of all urinary stones are seen in patients aged < 18 years. As a result of malnutrition and racial factors, paediatric urolithiasis remains an endemic disease in some areas (e.g., Turkey and the Far East); elsewhere, the rates are similar to those observed in developed countries [385-388].

For diagnostic procedures see Section 3.3.3.2, for acute decompression see Section 3.4.1.2.

3.4.6.1 Stone removal

Several factors must be considered when selecting treatment procedures for children. Compared to adults, children pass fragments more rapidly after SWL [52]. For endourological procedures, the smaller organs in children must be considered when selecting instruments for PNL or URS. Stone composition should be taken into account when selecting the appropriate procedure for stone removal (cystine stones are more resistant to SWL).

Summary of evidence	LE
Spontaneous passage of a stone is more likely in children than in adults [62].	4

3.4.6.1.1 Medical expulsive therapy in children

Medical expulsive therapy has already been discussed in Section 3.4.3.1.2 but not addressing children. Although the use of α -blockers is very common in adults, there are limited data to demonstrate their safety and efficacy in children; however, tamsulosin seems to support stone passage [65, 389-393].

3.4.6.1.2 Extracorporeal shock wave lithotripsy

Extracorporeal shock wave lithotripsy remains the least-invasive procedure for stone management in children [394-399].

Stone-free-rates of 67-93% in short-term and 57-92% in long-term follow-up studies have been reported. In children, compared with adults, SWL can achieve more effective disintegration of large stones, together with swifter and uncomplicated discharge of large fragments [396, 400]. As in adults, the slow delivery rate of shock waves may improve the stone clearance rates [400]. Stones located in calices, as well as in abnormal kidneys, and large stones, are more difficult to disintegrate and clear. The likelihood of urinary obstruction is higher in such cases, and children should be followed closely for the prolonged risk of urinary tract obstruction. The retreatment rate is 13.9-53.9%, and the need for ancillary procedures and/or additional interventions is 7-33% [396, 398].

The need for general anaesthesia during SWL depends on patient age and the lithotripter used. General or dissociative anaesthesia is administered in most children aged < 10 years, to prevent patient and stone motion and the need for repositioning [396, 398]. With modern lithotripters, intravenous sedation or patient-controlled analgesia have been used in selected co-operative older children [401] (LE: 2b). There are concerns regarding the safety and potential biological effects of SWL on immature kidneys and surrounding organs in children. However, during short- and long-term follow-up, no irreversible functional or morphological side effects of high-energy shock waves have been demonstrated. In addition, when the potential deterioration of renal function is taken into account (although transient), restricting the number of shock waves and the energy used during each treatment session helps protect the kidneys [402-405].

If the stone burden requires a ureteral stent, alternative procedures should be considered. Ureteral stents are seldom needed following SWL of upper tract stones, ureteral pre-stenting decreases the SFR after initial treatment [394-396].

Summary of evidence	LE
In children, the indications for shock wave lithotripsy are similar to those in adults; however, children	3
pass fragments more easily.	
Children with renal stones of a diameter up to 20 mm (~300 mm ²) are ideal candidates for shock wave	1b
lithotripsy.	

3.4.6.1.3 Endourological procedures

Improvement in intracorporeal lithotripsy devices and development of smaller instruments facilitate PNL and URS in children.

3.4.6.1.3.1 Percutaneous nephrolithotomy

Pre-operative evaluation and indications for PNL in children are similar to those in adults. Provided appropriate size instruments and US guidance are used, age is not a limiting factor, and PNL can be performed safely by experienced operators, with less radiation exposure, even for large and complex stones [406-410]. Stone-free rates are between 68% and 100% after a single session, and increase with adjunctive measures, such as second-look PNL, SWL and URS [406].

As for adults, tubeless PNL is safe in children, in well-selected cases [411, 412].

Summary of evidence	LE
In children, the indications for percutaneous nephrolithotomy are similar to those in adults.	1a

Recommendation

In children, perform percutaneous nephrolithotomy for the treatment of renal pelvic or calyceal stones with a diameter > 20 mm (~300 mm²). For ureteral stones, ureterorenoscopy may be an alternative, in case shockwave lithotripsy does not look promising.

GR

3.4.6.1.3.2 Ureterenoscopy

Although SWL is still the first-line treatment for most ureteral stones, it is unlikely to be successful for stones > 10 mm in diameter, or for impacted stones, calcium oxalate monohydrate or cystine stones, or stones in children with unfavourable anatomy and in whom localisation is difficult [413, 414].

If SWL is not promising, ureterenoscopy can be used. With the clinical introduction of smallercalibre instruments, this modality has become the treatment of choice for medium and larger distal ureteric stones in children [413-417].

Different lithotripsy techniques, including ultrasonic, pneumatic and laser lithotripsy, are all safe and effective (Section 3.4.3.1.4.1.2) [418, 419].

Recommendation	LE	GR
For intracorporeal lithotripsy, use the same devices as in adults (holmium: yttrium-aluminium-	3	С
garnet laser, pneumatic- and ultrasound lithotripters).		

Flexible URS

Despite concerns about the potential risks and complications related to endoscopic surgery of children's delicate ureter and collecting system, with the development of smaller size endoscopes, flexible ureterenoscopy (RIRS) has become an efficacious treatment modality for renal and ureteral stones [413, 419-421] and might be a particularly effective treatment option for lower calyx stones in the presence of unfavourable factors for SWL.

Similar to adults, routine stenting is not necessary before URS. However, leaving a ureteral stent for the subsequent session must be considered in case of failure of ureterenoscopy. Pre-stenting facilitates URS, increases SFR and decreases complication rates [422].

For large and complex kidney stones PNL has a higher SFR compared to RIRS, but RIRS is associated with less radiation exposure, lower complication rates and a shorter hospital stay [423]. The experience of the surgical team is of the utmost importance for the success of both endourological techniques.

3.4.6.1.3.3 Open or laparoscopic surgery

Most stones in children can be managed by SWL and endoscopic techniques. Therefore, the rate of open procedures has dropped significantly [424-426]. Indications for surgery include: failure of primary therapy for stone removal; very young children with complex stones; congenital obstruction that requires simultaneous surgical correction; severe orthopaedic deformities that limit positioning for endoscopic procedures; and abnormal kidney position [394, 395, 407]. Open surgery can be replaced by laparoscopic procedures in experienced hands [425, 426].

3.4.6.1.3.4 Special considerations on recurrence prevention

All paediatric stone formers need metabolic evaluation and recurrence prevention with respect to the detected stone type. In radiolucent stones oral chemolysis may be considered as an alternative to SWL [427]. In the case of obstructive pathology in association with the established metabolic abnormalities, treatment should not be delayed. Children are in the high-risk group for stone recurrence [65, 428] (Chapter 4).

4. FOLLOW UP: METABOLIC EVALUATION AND RECURRENCE PREVENTION

4.1 General metabolic considerations for patient work-up

4.1.1 Evaluation of patient risk

After stone passage, every patient should be assigned to a low- or high-risk group for stone formation (Figure 4.1).

For correct classification, two items are mandatory:

- reliable stone analysis by infrared spectroscopy or X-ray diffraction;
- basic analysis (Section 3.3.2).

Figure 4.1 Assignment of patients to low- or high-risk groups for stone formation

Only high-risk stone formers require specific metabolic evaluation. Stone type is the deciding factor for further diagnostic tests. The different stone types include:

- calcium oxalate;
- calcium phosphate;
- uric acid;
- ammonium urate;
- struvite (and infection stones);
- cystine;
- xanthine;
- 2,8-Dihydroxyadenine;
- drug stones;
- stones of unknown composition.

4.1.2 Urine sampling

Specific metabolic evaluation requires collection of two consecutive 24-hour urine samples [429, 430]. The collecting bottles should be prepared with 5% thymol in isopropanol or stored at < 8°C during collection to prevent the risk of spontaneous crystallisation in the urine [431, 432]. Pre-analytical errors can be minimised by carrying out urinalysis immediately after collection. Alternatively, boric acid (10 g powder per urine container) can also be used. The collecting method should be chosen in close cooperation with the particular laboratory. Urine pH should be assessed during collection of freshly voided urine four times daily [16, 431] using sensitive pH-dipsticks or a pH-meter.

Spot urine samples are an alternative method of sampling, particularly when 24-hours urine collection is difficult, for example, in non-toilet trained children [433]. Spot urine studies normally link the excretion rates to creatinine [433], but these are of limited use because the results may vary with collection time and patients' sex, body weight and age.

4.1.3 Timing of specific metabolic work-up

For the initial specific metabolic work-up, the patient should stay on a self-determined diet under normal daily conditions and should ideally be stone free for at least twenty days [434].

Follow-up studies are necessary in patients taking medication for recurrence prevention [435]. The first followup 24-hour urine measurement is suggested eight-twelve weeks after starting pharmacological prevention of stone recurrence. This enables drug dosage to be adjusted if urinary risk factors have not normalised, with further 24-hour urine measurements if necessary. Once urinary parameters have been normalised, it is sufficient to perform 24-hour urine evaluation every twelve months. The panel realise that on this issue there is only very limited published evidence. The Urolithiasis Guidelines Panel aim to set up a SR on the ideal timing of the 24-hour urine collection.

4.1.4 Reference ranges of laboratory values

Tables 4.1 - 4.4 provide the internationally accepted reference ranges for the different laboratory values in serum and urine.

Blood parameter	Reference range				
Creatinine	20-100 µmol/L	20-100 µmol/L			
Sodium	135-145 mmol/L				
Potassium	3.5-5.5 mmol/L				
Calcium	2.0-2.5 mmol/L (total calcium)				
	1.12-1.32 mmol/L (ionised calcium)				
Uric acid	119-380 µmol/L				
Chloride	98-112 mmol/L				
Phosphate	0.81-1.29 mmol/L				
Blood gas analysis	рН	7.35-7.45			
	pO ₂	80-90 mmHg			
	pCO ₂	35-45 mmHg			
	HCO ₃	22-26 mmol/L			
	BE	± 2 mmol/L			

Table 4.1: Normal laboratory values for blood parameters in adults [436]

BE = base excess (loss of buffer base to neutralise acid); HCO = bicarbonate; PCO = partial pressure of carbon dioxide; PO = partial pressure of oxygen.

4.1.5 Risk indices and additional diagnostic tools

Several risk indices have been developed to describe the crystallisation risk for calcium oxalate or calcium phosphate in urine [437-440]. However, clinical validation of these risk indices for recurrence prediction or therapy improvement is ongoing.

Table 4.2: Normal laboratory values for urinary parameters in adults

Urinary Parameters	Reference ranges and limits for medical attention		
рН	Constantly > 5.8 (suspicious of renal tubular acidosis)		
	Constantly > 7.0 (suspicious of infection)		
	Constantly \leq 5.8 (suspicious of acidic arrest)		
Specific weight	> 1.010		
Creatinine	7-13 mmol/day females		
	13-18 mmol/day males		
Calcium	> 5.0 mmol/day (see Fig. 4.2)		
	\geq 8.0 mmol/day (see Fig. 4.2)		
Oxalate	> 0.5 mmol/day (suspicious of enteric hyperoxaluria)		
	\geq 1.0 mmol/day (suspicious of primary hyperoxaluria)		
Uric acid	> 4.0 mmol/day (women), 5 mmol/day (men)		
Citrate	< 2.5 mmol/day		
Magnesium	< 3.0 mmol/day		
Inorganic phosphate	> 35 mmol/day		
Ammonium	> 50 mmol/day		
Cystine	> 0.8 mmol/day		

Table 4.3: Normal values for spot urine samples: creatinine ratios (solute/creatinine) in adults [441]

Parameter/Patient age	Ratio of solute to creatinine	Units
Calcium	mol/mol	mg/mg
< 12 months	< 2.0	0.81
1-3 years	< 1.5	0.53
1-5 years	< 1.1	0.39
5-7 years	< 0.8	0.28
> 7 years	< 0.6	0.21
Oxalate	mol/mol	mg/g
0-6 months	< 325-360	288-260
7-24 months	< 132-174	110-139
2-5 years	< 98-101	80
5-14 years	< 70-82	60-65
> 16 years	< 40	32
Citrate	mol/mol	g/g
0-5 years	> 0.25	0.42
> 5 years	> 0.15	0.25
Magnesium	mol/mol	g/g
	> 0.63	> 0.13
Uric acid	< 0.56 mg/dl (33 imol/L) per GFR (ra	tio x plasma creatinine)
> 2 years		

Table 4.4: Solute excretion in 24-hour urine samples in children [441]**

Calcium/24	Citrate/24 ho	our	Cystine/24 hour		Oxalate/24 hour		Urate/24 hour	
hour								
All age groups	Boys	Girls	< 10 years	> 10 years	All age	< 1 year	1-5 years	> 5 years
					groups			
< 0.1 mmol/kg/	> 1.9 mmol/	> 1.6 mmol/	< 55 µmol/	< 200 µmol/	< 0.5 mmol/	< 70 µmol/	< 65 mµmol/	< 55 µmol/
24 h	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	kg/24 h	kg/24 h	kg/24 h
< 4 mg/kg/24 h	> 365 mg/	> 310 mg/	< 13 mg/	< 48 mg/	< 45 mg /	< 13 mg/	< 11 mg/	< 9.3 mg/
	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	1.73 m²/24 h	kg/24 h	kg/24 h	kg/24 h

**24 h urine parameters are diet and gender dependent and may vary geographically.

4.2 General considerations for recurrence prevention

All stone formers, independent of their individual risk, should follow the preventive measures in Table 4.5. The main focus of these is normalisation of dietary habits and lifestyle risks. Stone formers at high risk need specific prophylaxis for recurrence, which is usually pharmacological treatment based on stone analysis.

Table 4.5: General preventive measures

Fluid intake (drinking advice)	Fluid amount: 2.5-3.0 L/day
	Circadian drinking
	Neutral pH beverages
	Diuresis: 2.0-2.5 L/day
	Specific weight of urine: < 1010
Nutritional advice for a balanced diet	Balanced diet*
	Rich in vegetables and fibre
	Normal calcium content: 1-1.2 g/day
	Limited NaCl content: 4-5 g/day
	Limited animal protein content: 0.8-1.0 g/kg/day
Lifestyle advice to normalise general risk factors	BMI: retain a normal BMI level
	Adequate physical activity
	Balancing of excessive fluid loss

Caution: The protein need is age dependent; therefore, protein restriction in childhood should be handled carefully.

* Avoid excessive consumption of vitamin supplements.

4.2.1 Fluid intake

An inverse relationship between high fluid intake and stone formation has been repeatedly demonstrated [442-444]. The effect of fruit juices is mainly determined by the presence of citrate or bicarbonate [445]. If hydrogen ions are present, the net result is neutralisation. However, if potassium is present, both pH and citrate are increased [446, 447]. One large fair-quality RCT randomly assigned men with more than one past renal stone of any type and soft drink consumption of at least 160 mL/day to reduced soft drink intake or no treatment. Although the intervention significantly reduced the risk for symptomatic recurrent stones (RR: 0.83; CI: 0.71-0.98), the level of evidence for this outcome was low because results were from only one trial [444, 448].

4.2.2 **Diet**

A common sense approach to diet should be taken, that is, a mixed balanced diet with contributions from all food groups, without any excesses [444, 449, 450].

Fruits, vegetables and fibres: fruit and vegetable intake should be encouraged because of the beneficial effects of fibre, although the role of the latter in preventing stone recurrences is debatable [451-454]. The alkaline content of a vegetarian diet also increases urinary pH.

Oxalate: excessive intake of oxalate-rich products should be limited or avoided to prevent high oxalate load [445], particularly in patients who have high oxalate excretion.

Vitamin C: although vitamin C is a precursor of oxalate, its role as a risk factor in calcium oxalate stone formation remains controversial [455]. However, it seems wise to advise calcium oxalate stone formers to avoid excessive intake.

Animal protein: should not be taken in excess [456, 457] and limited to 0.8-1.0 g/kg body weight. Excessive consumption of animal protein has several effects that favour stone formation, including hypocitraturia, low urine pH, hyperoxaluria and hyperuricosuria.

Calcium intake: should not be restricted unless there are strong reasons due to the inverse relationship between dietary calcium and stone formation [452, 458]. The daily requirement for calcium is 1,000 to 1,200 mg [16]. Calcium supplements are not recommended except in enteric hyperoxaluria, when additional calcium should be taken with meals to bind intestinal oxalate [444, 457, 459]. Older adults, who do not have a history of renal stones but who take calcium supplements should ensure adequate fluid intake since it may prevent increases in urine calcium concentration, and thereby reduce or eliminate any increased risk of renal stones formation associated with calcium supplement use [460].

Sodium: the daily sodium (NaCl) intake should not exceed 3-5 g [16]. High intake adversely affects urine composition:

- calcium excretion is increased by reduced tubular reabsorption;
- urinary citrate is reduced due to loss of bicarbonate;
- increased risk of sodium urate crystal formation.

Calcium stone formation can be reduced by restricting sodium and animal protein [456, 457]. A positive correlation between sodium consumption and risk of first-time stone formation has been confirmed only in women [458, 461]. There have been no prospective clinical trials on the role of sodium restriction as an independent variable in reducing the risk of stone formation.

Urate: intake of purine-rich food should be restricted in patients with hyperuricosuric calcium oxalate [462, 463] and uric acid stones. Intake should not exceed 500 mg/day [16].

4.2.3 Lifestyle

Lifestyle factors may influence the risk of stone formation, for example, obesity [464] and arterial hypertension [465, 466].

4.2.4 **Recommendations for recurrence prevention**

Recommendations	LE	GR
Advise patients that a generous fluid intake is to be maintained, allowing for a 24-hour urine	1b	А
volume > 2.5 L.		
Advise patients with a small urine volume to increase their fluid intake.	1b	а

4.3 Stone-specific metabolic evaluation and pharmacological recurrence prevention

4.3.1 Introduction

Pharmacological treatment is necessary in patients at high risk for recurrent stone formation. The ideal drug should halt stone formation, have no side effects, and be easy to administer. Each of these aspects is important to achieve good compliance. Table 4.6 highlights the most important characteristics of commonly used medication.

Table 4.6: Pharmacological substances used for stone prevention - characteristics, specifics and dosage

Agent	Rationale	Dose	Specifics and side effects	Stone type	Ref
Alkaline citrates	Alkalinisation Hypocitraturia Inhibition of calcium oxalate crystallisation	5-12 g/d (14-36 mmol/d) Children: 0.1-0.15 g/kg/d	Daily dose for alkalinisation depends on urine pH	Calcium oxalate Uric acid Cystine	[49, 444, 467-474]
Allopurinol	Hyperuricosuria Hyperuricaemia	100-300 mg/d Children: 1-3 mg/kg/d	100 mg in isolated hyperuricosuria Renal insufficiency demands dose correction	Calcium oxalate Uric acid Ammonium urate 2,8-Dihydroxyadenine	[475-479]
Calcium	Enteric hyperoxaluria	1000 mg/d	Intake 30 min before meals	Calcium oxalate	[457-459]
Captopril	Cystinuria Active decrease of urinary cystine levels	75-150 mg	Second-line option due to significant side effects	Cystine	[480, 481]
Febuxostat	Hyperuricosuria Hyperuricaemia	80-120 mg/d	Acute gout contraindicated, pregnancy, xanthine stone formation	Calcium oxalate Uric acid	[482, 483]
L-Methionine	Acidification	600-1500 mg/d	Hypercalciuria, bone demineralisation, systemic acidosis. No long-term therapy.	Infection stones Ammonium urate Calcium phosphate	[49, 484, 485]
Magnesium	Isolated hypomagnesiuria Enteric hyperoxaluria	200-400 mg/d Children: 6 mg/kg/d	Renal insufficiency demands dose correction. Diarrhoea, chronic alkali losses, hypocitraturia.	Calcium oxalate	[486, 487] low evidence
Sodium bicarbonate	Alkalinisation Hypocitraturia	4.5 g/d		Calcium oxalate Uric acid, Cystine	[488]
Pyridoxine	Primary hyperoxaluria	Initial dose 5 mg/kg/d Max. 20 mg/kg/d	Polyneuropathia	Calcium oxalate	[489]
Thiazide (Hydrochlorothiazide)	Hypercalciuria	25-50 mg/d Children: 0.5-1 mg/kg/d	Risk for agent- induced hypotonic blood pressure, diabetes, hyperuricaemia, hypokalaemia, followed by intracellular acidosis and hypocitraturia.	Calcium oxalate Calcium phosphate	[49, 486, 490-498]
Tiopronin	Cystinuria Active decrease of urinary cystine levels	Initial dose 250 mg/d Max. 2000 mg/d	Risk for tachyphylaxis and proteinuria.	Cystine	[499-502]

4.4 Calcium oxalate stones

The criteria for identification of calcium oxalate stone formers with high recurrence risk are listed in Section 3.1.2.

4.4.1 Diagnosis

Blood analysis requires measurement of creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), uric acid, and parathyroid hormone (PTH) (and vitamin D) in the case of increased calcium levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight, calcium, oxalate, uric acid, citrate, sodium and magnesium.

4.4.2 Interpretation of results and aetiology

The diagnostic and therapeutic algorithm for calcium oxalate stones is shown in Figure 4.2 [49, 444, 468-470, 475-477, 482, 486-488, 490-497, 503-507].

The most common metabolic abnormalities associated with calcium stone formation are hypercalciuria, which affects 30-60% of adult stone formers, and hyperoxaluria (26-67%), followed by hyperuricosuria (15-46%), hypomagnesiuria (7-23%), and hypocitraturia (5-29%). However, ranges tend to differ based on ethnicity [503].

- Elevated levels of ionised calcium in serum (or total calcium and albumin) require assessment of intact PTH to confirm or exclude suspected hyperparathyroidism (HPT).
- "Acidic arrest" (urine pH constantly < 5.8) may promote co-crystallisation of uric acid and calcium oxalate.
- Similarly, increased uric acid excretion (> 4 mmol/day in adults or > 12 mg/kg/day in children) can act as a
 promoter.
- Urine pH levels constantly > 5.8 in the day profile indicate renal tubular acidosis (RTA), provided UTI has been excluded. An ammonium chloride loading test confirms RTA and identifies RTA subtype (Section 4.6.5).
- Hypercalciuria may be associated with normocalcemia (idiopathic hypercalciuria, or granulomatous diseases) or hypercalcaemia (hyperparathyroidism, granulomatous diseases, vitamin D excess, or malignancy).
- Hypocitraturia (male < 1.7 mmol/d, female < 1.9 mmol/d) may be idiopathic or secondary to metabolic acidosis or hypokalaemia.
- Oxalate excretion > 0.5 mmol/day in adults (> 0.37 mmol/1.73 m²/day in children) confirms hyperoxaluria.
 - primary hyperoxaluria (oxalate excretion mostly > 1 mmol/day), appears in three genetically determined forms;
 - secondary hyperoxaluria (oxalate excretion > 0.5 mmol/day, usually < 1 mmol/day), occurs due to intestinal hyperabsorption of oxalate or extreme dietary oxalate intake;
 - o mild hyperoxaluria (oxalate excretion 0.45-0.85 mmol/day), commonly found in idiopathic calcium oxalate stone formers.
- Hypomagnesuria (< 3.0 mmol/day) may be related to poor dietary intake or to reduced intestinal absorption (chronic diarrhoea).

Figure 4.2: Diagnostic and therapeutic algorithm for calcium oxalate stones

¹ Be aware of excess calcium excretion.

 2 tid = three times/day (24h).

³ No magnesium therapy for patients with renal insufficiency.

⁴ There is no evidence that combination therapy (thiazide + citrate) (thiazide + allopurinol) is superior to thiazide therapy alone [490, 497].

⁵ Febuxostat 80 mg/d.

4.4.3 Specific treatment

General preventive measures are recommended for fluid intake and diet. Hyperoxaluric stone formers should consume foods with low oxalate content, whereas hyperuricosuric stone formers benefit from daily dietary reduction of purine. Figure 4.2 summarises the diagnostic algorithm and the pharmacological treatment of calcium oxalate stones [49, 444, 468-470, 475-477, 482, 486-488, 490-497, 503-507]. There is only low level evidence on the efficacy of preventing stone recurrence through pre-treatment stone composition and biochemistry measures, or on-treatment biochemistry measures [444].

4.4.4 **Recommendations for pharmacological treatment of patients with specific abnormalities in** *urine composition* (based on 24-hour urine samples)

Urinary risk factor	Suggested treatment	LE	GR

No abnormality identified	High fluid intake	2b	В

4.5 Calcium phosphate stones

Some calcium phosphate stone formers are at high risk of recurrence. Further information on identifying high-risk patients is provided in Section 3.1.2.

Calcium phosphate mainly appears in two completely different minerals: carbonate apatite and brushite. Carbonate apatite crystallisation occurs at a pH > 6.8 and may be associated with infection.

Brushite crystallises at an optimum pH of 6.5-6.8, at high urinary concentrations of calcium (> 8 mmol/day) and phosphate (> 35 mmol/day). Its occurrence is not related to UTI.

Possible causes of calcium phosphate stones include HPT, RTA and UTI; each of which requires different therapy.

4.5.1 Diagnosis

Diagnosis requires blood analysis for: creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), and PTH (in the case of increased calcium levels). Urinalysis includes measurement of: volume, urine pH profile, specific weight, calcium, phosphate and citrate.

4.5.2 Interpretation of results and aetiology

General preventive measures are recommended for fluid intake and diet. The diagnostic and therapeutic algorithm for calcium phosphate stones is shown in Figure 4.3.

Figure 4.3: Diagnostic and therapeutic algorithm for calcium phosphate stones

HPT = hyperparathyroidism; RTA = renal tubular acidosis; UTI = urinary tract infection.

4.5.3 *Pharmacological therapy* [49, 444, 490, 491, 495, 507]

Hyperparathyroidism and RTA are common causes of calcium phosphate stone formation. Although most patients with primary HPT require surgery, RTA can be corrected pharmacologically. If primary HPT and RTA have been excluded, pharmacotherapy for calcium phosphate calculi depends on effective reduction of urinary calcium levels using thiazides. If urine pH remains constantly > 6.2, urinary acidification with L-methionine may be beneficial; however, it is not commonly used and needs monitoring for systemic acidosis development. For

infection-associated calcium phosphate stones, it is important to consider the guidance given for infection stones.

4.5.4 **Recommendations for the treatment of calcium phosphate stones**

Urinary risk factor and suggested treatment		GR
Prescribe thiazide in case of hypercalciuria.	1a	А
Advise patients to acidify their urine in case of inadequate urine pH.	3-4	С
Prescribe antibiotics in case of a urinary tract infection.	3-4	С

4.6 Disorders and diseases related to calcium stones

4.6.1 Hyperparathyroidism [508-511]

Primary HPT is responsible for an estimated 5% of all calcium stone formation. Renal stones occur in approximately 20% of patients with primary HPT. Elevated levels of PTH significantly increase calcium turnover, leading to hypercalcaemia and hypercalciuria. Serum calcium may be mildly elevated and serum PTH may be within the upper normal limits, therefore, repeated measurements may be needed; preferably with the patient fasting. Stones of HPT patients may contain both calcium oxalate and calcium phosphate.

If HPT is suspected, neck exploration should be performed to confirm the diagnosis. Primary HPT can only be cured by surgery.

4.6.2 Granulomatous diseases [511]

Granulomatous diseases, such as sarcoidosis, may be complicated by hypercalcaemia and hypercalciuria secondary to increased calcitriol production. The latter is independent of PTH control, leading to increased calcium absorption in the gastrointestinal tract and suppression of PTH. Treatment focusses on the activity of the granulomatous diseases and may require steroids, hydroxychloroquine or ketoconazole. Treatment should be reserved for the specialist.

4.6.3 Primary hyperoxaluria [489]

Patients with primary hyperoxaluria (PH) should be referred to specialised centres, as successful management requires an experienced interdisciplinary team. The main therapeutic aim is to reduce endogenous oxalate production, which is increased in patients with PH. In approximately one-third of patients with PH type I, pyridoxine therapy normalises or significantly reduces urinary oxalate excretion. The goal of adequate urine dilution is achieved by adjusting fluid intake to 3.5-4.0 L/day in adults (children 1.5 L/m² body surface area) and following a circadian drinking regimen.

Therapeutic options for preventing calcium oxalate crystallisation include hyperdiuresis, alkaline citrates and magnesium. However, in end-stage renal failure, PH requires simultaneous liver-kidney transplantation.

Treatment regimens are:

- pyridoxine in PH type I: 5-20 mg/kg/day according to urinary oxalate excretion and patient tolerance;
- alkaline citrate: 9-12 g/day in adults, 0.1-0.15 meq/kg/day in children;
- magnesium: 200-400 mg/day (no magnesium in the case of renal insufficiency).

Urinary risk factor and suggested management of primary hyperoxaluria		GR
Refer patients diagnosed with primary hyperoxaluria to a specialised centre where		
multidisciplinary care can be provided.		
Prescribe pyridoxine for primary hyperoxaluria.	3	В

4.6.4 Enteric hyperoxaluria [459, 512]

Enteric hyperoxaluria is a particularly problematic condition in patients with intestinal malabsorption of fat. This abnormality is associated with a high risk of stone formation, and is seen after intestinal resection and malabsorptive bariatric surgery and in Crohn's disease and pancreas insufficiency. In addition to hyperoxaluria, these patients usually present with hypocitraturia due to loss of alkali. Urine pH is usually low, as are urinary calcium and urine volume. All these abnormalities contribute to high levels of supersaturation with calcium oxalate, crystalluria, and stone formation.

Specific preventive measures are:

• restricted intake of oxalate-rich foods;

- restricted fat intake;
- calcium supplementation at meal times to enable calcium oxalate complex formation in the intestine [459, 512];
- sufficient fluid intake to balance intestinal loss of water caused by diarrhoea;
- alkaline citrates to raise urinary pH and citrate.

Urinary risk factor and suggested management of enteric hyperoxaluria		GR
Prescribe potassium citrate.	4	С
Advise patients to take a calcium supplement.	2	В
Advise patients to follow a diet with a low fat and oxalate content.	3	В

4.6.5 Renal tubular acidosis [513, 514]

Renal tubular acidosis is caused by severe impairment of proton or bicarbonate handling along the nephron. Kidney stone formation most probably occurs in patients with distal RTA type I. Figure 4.4 outlines the diagnosis of RTA. Table 4.7 shows acquired and inherited causes of RTA.

Figure 4.4: Diagnosis of renal tubular acidosis

** An alternative Ammonium Chloride loading test using NH₄Cl load with 0.05 g/kg body weight over three days might provide similar results and may be better tolerated by the patient. A second alternative in these cases could be the furosemide acidification test.

Renal tubular acidosis can be acquired or inherited. Reasons for acquired RTA can be obstructive uropathy, recurrent pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, idiopathic hypercalciuria, and primary parathyroidism; it may also be drug-induced (e.g. zonisamide). Table 4.7 shows the inherited causes of RTA.

Table 4.7: Inherited causes of renal tubular acidosis

Type - inheritance	Gene/gene product/function	Phenotype
Autosomal dominant	SLC4A1/AE1/CI-bicarbonate	Hypercalciuria, hypokalaemia,
	exchanger	osteomalacia
Autosomal recessive with hearing	ATP6V1B1/B1 subunit of vacuolar	Hypercalciuria, hypokalaemia,
loss	H-ATPase/proton secretion	rickets
Autosomal recessive	ATP6V0A4/A4 subunit of vacuolar	Hypercalciuria, hypokalaemia,
	H-ATPase/proton secretion	rickets

The main therapeutic aim of RTA treatment is restoring a normal acid-base equilibrium. Despite the alkaline pH of urine in RTA, alkalinisation using alkaline citrates or sodium bicarbonate is key to normalising the metabolic changes (intracellular acidosis) responsible for stone formation (Table 4.8). The alkali load reduces tubular reabsorption of citrate, which in turn normalises citrate excretion and simultaneously reduces calcium turnover. Therapeutic success can be monitored by venous blood gas analysis (base excess: $\pm 2.0 \text{ mmol/L}$) in complete RTA. If excessive calcium excretion (> 8 mmol/day) persists after re-establishing acid-base equilibrium, thiazides may lower urinary calcium excretion.

Table 4.8: Pharmacological treatment of renal tubular acidosis

Biochemical risk factor	Rationale for pharmacological	Medication
	therapy	
Hypercalciuria	Calcium excretion > 8 mmol/day	Hydrochlorothiazide,
		- in adults: 25 mg/day initially, up to
		50 mg/day
		- in children: 0.5-1 mg/kg/day
		Alternatives in adults:
		Chlorthalidone 25 mg/d
		Indapamide 2.5 mg/d
Inadequate urine pH	Intracellular acidosis in nephron	Alkaline citrate, 9-12 g/day divided
		in three doses
		OR

		times daily

Urinary risk factor and suggested management of renal tubular acidosis	LE	GR
Prescribe potassium citrate for distal renal tubular acidosis.	2b	В
Prescribe thiazide + potassium citrate for hypercalciuria.	1a	А

4.6.6 Nephrocalcinosis [441]

Nephrocalcinosis (NC) refers to increased crystal deposition within the renal cortex or medulla, and occurs alone or in combination with renal stones. There are various metabolic causes. The main risk factors are: HPT, PH, RTA, vitamin D metabolic disorders, idiopathic hypercalciuria and hypocitraturia, and genetic disorders, including Dent's disease, Bartter's syndrome and Medullary sponge kidney. The many causes of NC means there is no single standard therapy. Therapeutic attention must focus on the underlying metabolic or genetic disease, while minimising the biochemical risk factors.

4.6.6.1 Diagnosis

Diagnosis requires the following blood analysis: PTH (in the case of increased calcium levels), vitamin D and metabolites, vitamin A, sodium, potassium, magnesium, chloride, and blood gas analysis. Urinalysis should investigate: urine pH profile (minimum four times daily), daily urine volume, specific weight of urine, and levels of calcium, oxalate, phosphate, uric acid, magnesium and citrate.

4.7 Uric acid and ammonium urate stones

All uric acid and ammonium urate stone formers are considered to be at high risk of recurrence [16]. Uric acid nephrolithiasis is responsible for approximately 10% of renal stones [515]. They are associated with hyperuricosuria or low urinary pH. Hyperuricosuria may be a result of dietary excess, endogenous

overproduction (enzyme defects), myeloproliferative disorders, tumour lysis syndrome, drugs, gout or catabolism [516]. Low urinary pH may be caused by decreased urinary ammonium excretion (insulin resistance or gout), increased endogenous acid production (insulin resistance, metabolic syndrome, or exercise-induced lactic acidosis), increased acid intake (high animal protein intake), or increased base loss (diarrhoea) [516].

Ammonium urate stones are extremely rare, comprising < 1% of all types of urinary stones. They are associated with UTI, malabsorption (inflammatory bowel disease and ileostomy diversion or laxative abuse), potassium deficiency, hypokalaemia and malnutrition.

Suggestions on uric acid and ammonium urate nephrolithiasis are based on level 3 and 4 evidence.

4.7.1 Diagnosis

Figure 4.5 shows the diagnostic and therapeutic algorithm for uric acid and ammonium urate stones. Blood analysis requires measurement of creatinine, potassium and uric acid levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight of urine, and uric acid level. Urine culture is needed in the case of ammonium urate stones.

4.7.2 Interpretation of results

Uric acid and ammonium urate stones form under completely different biochemical conditions. Acidic arrest (urine pH constantly < 5.8) promotes uric acid crystallisation.

Hyperuricosuria is defined as uric acid excretion > 4 mmol/day in adults or > 0.12 mmol/kg/day in children. Hyperuricaemia may be present, but there is only weak evidence for its association with stone formation.

Hyperuricosuric calcium oxalate stone formation can be distinguished from uric acid stone formation by: urinary pH, which is usually > 5.5 in calcium oxalate stone formation and < 5.5 in uric acid stone formation and occasional absence of hyperuricosuria in patients with pure uric acid stones [517, 518]. Ammonium urate crystals form in urine at pH > 6.5, at high uric acid concentration when ammonium is present to serve as a cation [519-521].

4.7.3 Specific treatment

General preventive measures are recommended for fluid intake and diet. Hyperuricosuric stone formers benefit from purine reduction in their daily diet. Figure 4.5 describes pharmacological treatment [16, 433, 515-527]. For uric acid stones, allopurinol may change the stone composition distribution in patients with gout to a pattern similar to that in stone formers without gout [528].

Figure 4.5: Diagnostic and therapeutic algorithm for uric acid- and ammonium urate stones

¹ d: day.

² tid: three times a day.

³ A higher pH may lead to calcium phosphate stone formation.

⁴ In patients with high uric acid excretion, allopurinol may be helpful.

4.8 Struvite and infection stones

All infection-stone formers are deemed at high risk of recurrence. Struvite stones represent 2-15% of the stones sent for analysis. Stones that contain struvite may originate *de novo* or grow on pre-existing stones, which are infected with urea-splitting bacteria [529]. There are several factors predisposing patients to struvite stone formation (Table 4.9) [530].

4.8.1 Diagnosis

Blood analysis requires measurement of creatinine, and urinalysis requires repeat urine pH measurements and urine culture.

Interpretation

Infection stones contain the following minerals: struvite and/or carbonate apatite and/or ammonium urate. Urine culture typically provides evidence for urease-producing bacteria, which increase ammonia ions and develop alkaline urine (Table 4.10). Carbonate apatite starts to crystallise at a urine pH level of 6.8. Struvite only precipitates at pH > 7.2 [531, 532]. *Proteus mirabilis* accounts for more than half of all urease-positive UTIs [533, 534].

4.8.2 Specific treatment

General preventive measures are recommended for fluid intake and diet. Specific measures include complete surgical stone removal [530], short- or long-term antibiotic treatment [535], urinary acidification using methionine [484] or ammonium chloride [536], and advice to restrict intake of urease [537, 538]. For severe infections, acetohydroxamic acid may be an option [537, 538] (Figure 4.6); however, it is not licensed/available in all European countries.

4.8.3 **Recommendations for therapeutic measures of infection stones**

Recommendations	LE	GR
Surgically remove the stone material as completely as possible.	3-4	A*
Prescribe a short-term antibiotic course.	3	В
Prescribe a long-term antibiotic course in case of recurrent infections.	3	В
Prescribe ammonium chloride, 1 g, two or three times daily to ensure urinary acidification.	3	В
Prescribe methionine, 200-500 mg, one-three times daily, as an alternative, to ensure urinary acidification.	3	В
Consider prescription of urease inhibitors in case of severe infection (if licensed).	1b	А

* When nationally available.

bid = twice a day; tid = three times a day.

4.9 Cystine stones

Cystine stones account for 1-2% of all urinary stones in adults and 6-8% of the stones reported in paediatric studies [26, 539]. All cystine stone formers are deemed at high risk of recurrence.

4.9.1 Diagnosis

Blood analysis includes measurement of creatinine, and urinalysis includes measurement of urine volume, pH profile, specific weight, and cystine.

Interpretation

- Cystine is poorly soluble in urine and crystallises spontaneously within the physiological urinary pH range.
- Cystine solubility depends strongly on urine pH: at pH 6.0, the limit of solubility is 1.33 mmol/L.
- Routine analysis of cystine is not suitable for therapeutic monitoring.
- Regardless of phenotype or genotype of the cystinuric patient, the clinical manifestations are the same [540].
- There is no role for genotyping patients in the routine management of cystinuria [541, 542].
- Reductive therapy targets the disulphide binding in the cysteine molecule. For therapy monitoring, it is
 essential to differentiate between cystine, cysteine and drug-cysteine complexes. Only high-performance
 liquid chromatography (HPLC)-based analysis differentiates between the different complexes formed by
 therapy.
- Diagnosis is established by stone analysis. The typical hexagonal crystals are detectable in only 20-25% of urine specimens from patients with cystinuria [543].

- The cyanide nitroprusside colorimetric qualitative test detects the presence of cystine at a threshold concentration of 75 mg/L, with a sensitivity of 72% and specificity of 95%. False-positive results in patients with Fanconi's syndrome, homocystinuria, or those taking various drugs, including Infection stones
- Quantitative 24-hour urinary cystine excretion confirms the diagnosis in the absence of stone analysis.
- Levels above 30 mg/day are considered abnormal [544, 545].

4.9.2 Specific treatment

General preventative measures for fluid intake and diet are recommended. A diet low in methionine may theoretically reduce urinary excretion of cystine; however, patients are unlikely to comply sufficiently with such a diet. A restricted intake of sodium is more easily achieved and is more effective in reducing urinary cystine. Patients are usually advised to avoid sodium consumption > 2 g/day [546].

A high level of diuresis is of fundamental importance, aiming for a 24-hour urine volume of > 3 L [547].

A considerable fluid intake evenly distributed throughout the day is necessary.

4.9.2.1 Pharmacological treatment of cystine stones

The main therapeutic option for avoiding cystine crystallisation is to maintain urine pH > 7.5, to improve cystine solubility and ensure appropriate hydration with a minimum of 3.5 L/day in adults, or 1.5 L/m² body surface area in children.

Free cystine concentration can be decreased by reductive substances, which act by splitting the disulphide binding of cysteine.

Tiopronin is currently the best choice for cystine reduction. However, side effects often lead to treatment termination, for example, when nephrotic syndrome develops, or poor compliance, especially with long-term use.

After carefully considering the risk of early tachyphylaxis, putting into place a dose-escape phenomenon for long-term use, and recurrence risk, tiopronin is recommended at cystine levels > 3.0 mmol/day or in the case of recurring stone formation, notwithstanding other preventive measures.

Therapeutic measures	LE	GR
Urine dilution	3	В
Advise patients to increase their fluid intake so that 24-hour urine volume exceeds 3 L.		
Intake should be > 150 mL/h.		
Alkalinisation	3	В
For patients with cystine excretion < 3 mmol/day, prescribe potassium citrate 3-10 mmol two		
or three times daily, to achieve $pH > 7.5$.		
Complex formation with cystine	3	В
For patients with cystine excretion, > 3 mmol/day, or when other measures are insufficient:		
prescribe in addition to other measures tiopronin, 250-2,000 mg/day.		

4.10 2,8-Dihydroxyandenine stones and xanthine stones [16]

All 2,8-Dihydroxyadenine and xanthine stone formers are considered to be at high risk of recurrence. Both stone types are rare. Diagnosis and specific prevention are similar to those for uric acid stones.

4.10.1 2,8-Dihydroxyadenine stones

A genetically determined defect of adenine phosphoribosyl transferase causes high urinary excretion of poorly soluble 2,8-Dihydroxyadenine. High-dose allopurinol or febuxostat are important options, but should be given with regular monitoring.

4.10.2 Xanthine stones

Patients who form xanthine stones usually show decreased levels of serum uric acid. There is no available pharmacological intervention.

4.10.3 Fluid intake and diet

Recommendations for general preventive measures apply. Pharmacological intervention is difficult, therefore, high fluid intake ensures optimal specific weight levels of urine < 1.010. A purine-reduced diet decreases the risk of spontaneous crystallisation in urine.

4.11 Drug stones [49]

Drug stones are induced by pharmacological treatment [548] (Table 4.11). Two types exist:

- stones formed by crystallised compounds of the drug;
- stones formed due to unfavourable changes in urine composition under drug therapy.

Table 4.11: Compounds that cause drug stones

Active compounds crystallising in urine Allopurinol/oxypurinol Amoxicillin/ampicillin Ceftriaxone Quinolones Ephedrine Indinavir Magnesium trisilicate Sulphonamides Triamterene Zonisamide Substances impairing urine composition Acetazolamide Allopurinol Aluminium magnesium hydroxide Ascorbic acid Calcium Furosemide Laxatives Methoxyflurane Vitamin D Topiramate

4.12 Matrix Stones

Pure matrix stones are extremely rare with less than 70 cases described in the literature. They are more prevalent in females. The main risk factors are recurrent UTIs, especially due to *Proteous mirabilis* or *Escherichia coli*, previous surgery for stone disease, chronic renal failure and haemodialysis. Complete endourological removal, frequently via the percutaneous approach, is critical. Given the rarity of matrix calculi a specific prophylactic regimen to minimise recurrence cannot be recommended. Eliminating infections and prophylactic use of antibiotics are most commonly proposed [233].

4.13 Unknown stone composition [15]

An accurate medical history is the first step towards identifying risk factors (Table 4.12).

Diagnostic imaging begins with US examination of both kidneys to establish whether the patient is stone free. Stone detection by US should be followed by KUB and unenhanced multislice CT in adults to differentiate between calcium-containing and non-calcium stones.

Blood analysis demonstrates severe metabolic and organic disorders, such as renal insufficiency, HPT or other hypercalcaemic states and hyperuricaemia. In children, hyperoxalaemia is additionally screened for.

Urinalysis is performed routinely with a dipstick test as described above. Urine culture is required if there are signs of infection.

Constant urine pH < 5.8 in the daily profile indicates acidic arrest, which may promote uric acid

crystallisation. Persistent urine pH > 5.8 in the daily profile indicates RTA, if UTI is excluded.

Microscopy of urinary sediment can help to discover rare stone types, because crystals of 2,8-Dihydroxyadenine, cystine and xanthine are pathognomonic for the corresponding disease. In cases in which the presence of cystine is doubtful, a cyanide nitroprusside colorimetric qualitative test can be used to detect the presence of cystine in urine, with a sensitivity of 72% and specificity of 95%. False-positive results are possible in patients with Fanconi's syndrome or homocystinuria, or in those taking various drugs, including ampicillin or sulfa-containing medication [549, 550].

Following this programme, the most probable stone type can be assumed and specific patient evaluation can follow. However, if any expulsed stone material is available, it should be analysed by diagnostic confirmation or correction.

Investigation	Rationale for investigation
Take a medical history	• Stone history (former stone events, family history)
	Dietary habits
	Medication chart
Perform diagnostic imaging	• Ultrasound in the case of a suspected stone
	 Unenhanced helical computed tomography
	Determination of Hounsfield units provides
	information about the possible stone composition
Perform a blood analysis	• Creatinine
	• Calcium (ionised calcium or total calcium + albumin)
	• Uric acid
Perform a urinalysis	• Urine pH profile (measurement after each voiding,
	minimum four times daily)
	Dipstick test: leukocytes, erythrocytes, nitrite,
	protein, urine pH, specific weight
	Urine cultures
	Microscopy of urinary sediment (morning urine)
	Cyanide nitroprusside test (cystine exclusion)
	Further examinations depend on the results of the
	investigations listed above.

Table 4.12: Recommendations for the assessment of patients with stones of unknown compos	ition
--	-------

6. CONFLICT OF INTEREST

All members of the Urolithiasis Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: <u>http://www.uroweb.org/guidelines/online-guidelines/</u>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.
